Abstract—Experimental results from HERA on diffractive vector meson production and their theoretical interpretation within microscopic QCD are reviewed with an emphasis on the BFKL color dipole and k_T-factorization approaches.

1. INTRODUCTION

1.1. The Motivation

The deep inelastic scattering (DIS) of leptons off hadrons is interpreted as a knockout of one of the charged partons of the target by hard Rutherford scattering followed by a complete shattering of the target nucleon or nucleus. One of major discoveries at the electron–proton collider HERA at DESY was the observation that the large rapidity gap events, in which the target nucleon emerges in the final state with a loss of a very small fraction of its energy-momentum, constitute a substantial and approximately scaling fraction of high-energy/small-x DIS of electrons and positrons on protons [1, 2]. Although the major features of such events and their cross sections have been correctly predicted within perturbative QCD [3], the very existence of large rapidity gap events for nuclear targets is nearly paradoxical. As well known, the deposition of dozen MeV energy is already sufficient to break up the target nucleus, still the theory predicts that for a sufficiently heavy nucleus and for the Bjorken variable $x \lesssim 10^{-3}$, the fraction of rapidity-gap DIS with retention of the target nucleus in exactly the ground state must be exactly 50% [4], and there is a direct evidence for that from the E665 Fermilab experiment [5]. The discovery of rapidity gaps at HERA has led to a renaissance of the physics of diffractive scattering in an entirely new domain, in which the large momentum transfer from leptons provides a hard scale. It also vindicated the early suggestions of Bjorken to look for hard diffraction in hadronic interactions [6] and stimulated a revival of the rapidity gap physics with hard triggers—large-$p_\perp$ jets, $W^\pm$-bosons, excitation of heavy flavors—at the proton–antiproton collider Tevatron (for the recent review, see [7–9] and refer-

ences therein). Whether the existence of such a hard scale makes the diffractive DIS tractable within the perturbative QCD or not has been a subject of intense theoretical and experimental research during the past decade or so. A good summary of the pre-1997 status of the vector meson production physics is found in the monograph of Crittenden [10]; the pre-1999 status of theoretical ideas on diffractive DIS was reviewed by Hebecker [11]; for the general introduction into the physics of diffractive scattering, see the recent books of Barone and Predazzi [12] and Forshaw and Ross [13].

The subject of this review is a special case of diffractive DIS—the exclusive production of vector mesons. One disclaimer is in order: we focus on the high-energy and/or very small-x regime dominated by the pQCD Pomeron exchange and, facing the size limitations, do not discuss very interesting low- to moderate-energy data from the HERMES Collaboration which are strongly affected by the nonvacuum exchanges (for the review and references, see [14]). In the past decade the topic of high-energy diffraction has been dominated by new fundamental data coming from the ZEUS and H1 experiments at HERA. The interest in the exclusive electro production of vector mesons is multifold. From the purely experimental point of view, the HERA experiments offer a prime example of diffractive scattering at energies much higher than were previously attainable. Furthermore, the self-analyzing decays of spin-1 vector mesons allow one to unravel the mechanism of diffraction in full complexity. Specifically, the HERA experiments for the first time gave unequivocal proof that the s-channel helicity nonconservation persists at the highest available energies [15, 16]. On the theoretical side, starting from the seminal papers on the color dipole approach by Kopeliovich, Zakharov *et al.* [17–21] and the related momentum space approach by Ryskin [22] and Brodsky *et al.* [23],

Fig. 1. The kinematics of DIS.

Fig. 2. The unitarity relation between DIS and forward Compton scattering.

it has been understood that the exclusive diffractive production of vector mesons in DIS is a genuinely hard phenomenon, whose major features can be described by pQCD. This can be understood in terms of the shrinkage of the photon with the increase of the hard scale [17, 18, 24], and because of this shrinkage, the diffractive production probes the hadronic properties of the photon and vector mesons at short distances. One of the direct manifestations of this photon shrinkage is a decrease of the diffraction slope with the increase of the hard scale [25, 26], which has for the first time been observed at HERA [27, 28] (for the earlier evidence from the NMC experiment, see [29]). Finally, the presence of the hard scale enables one to test the modern theoretical ideas on the mechanism of the t-channel exchange with vacuum quantum numbers, i.e., the QCD Pomeron. The way the QCD Pomeron is probed in diffractive vector meson production is similar to, but still different from that in the conventional inclusive DIS. For instance, large-t diffractive production of vector mesons probes the QCD Pomeron in a hard regime [30] inaccessible in inclusive DIS.

1.2. From Inclusive DIS to DVCS to Exclusive Vector Meson Production

To this end, recall the basics of inclusive DIS of leptons off nucleons

$$e(k)p(P) \longrightarrow e(k')X.$$

To the lowest order in QED, it is treated in the one-photon exchange approximation. The leptons serve as a source of virtual photons of energy ν and virtuality $Q^2 = -q^2$ (the scattering kinematics and the 4-momenta are shown in Fig. 1), and the fundamental process is the virtual photoabsorption

$$\gamma^*(Q^2)p(P) \longrightarrow X.$$

In the fully inclusive DIS, only the scattered lepton is detected, and one sums over all the hadronic final states X. Then, the observed inclusive DIS cross section is proportional to the absorptive part of the forward, at vanishing momentum transfer Δ, virtual Compton scattering amplitude $\mathcal{T}_{\mu\nu}(\nu, Q_f^2, Q_{in}^2, \Delta = 0)$ shown in Fig. 2:
$$\gamma^*(Q^2)p(P) \longrightarrow \gamma^*(Q^2)p(P), \qquad (1)$$

and, invoking the optical theorem, can be cast in the form of the flux of virtual transverse (T) and scalar (longitudinal) (L) photons times the total photoabsorption cross sections σ_T and σ_L.

Now, take a closer look at the Compton scattering amplitude as a function of the virtuality of the incident- (*in*) and final- (*f*) state photons, Q_{in}^2 and Q_f^2, respectively. In fully inclusive DIS, this amplitude is accessible only for $Q_{in}^2 = Q_f^2 = Q^2$ and at vanishing momentum transfer $\Delta = 0$. When continued analytically to $Q_f^2 = 0$, the amplitude $\mathcal{T}_{\mu\nu}(\nu, 0, Q^2)$ will describe the exclusive real photon production often referred to as the deeply virtual Compton scattering (DVCS) [31]

$$\gamma^*(Q^2)p(P) \longrightarrow \gamma p(P'), \qquad (2)$$

while the further continuation to $Q_f^2 = -m_V^2$ gives the amplitude of the exclusive vector meson production

$$\gamma^*(Q^2)p(P) \longrightarrow V(v)p(P'). \qquad (3)$$

Both DVCS and exclusive vector meson production can be studied experimentally by selecting a special final state $X = \gamma p(P')$ or $X = Vp(P')$, respectively. Furthermore, both reactions can be studied at the nonvanishing momentum transfer Δ, i.e., $t = -\Delta^2 \neq 0$ (for the definition of the kinematical variables, see Fig. 3).

The point inclusive of DIS, DVCS, and exclusive vector meson production is described by the same analytic function taken at different values of Q_f^2, suggests from the very outset the complementary probe of high-energy pQCD in the three reactions (1), (2), and (3). For instance, in the forward, $\Delta = 0$, Compton scattering probed in inclusive DIS, the helicity-flip amplitudes vanish for the kinematical reason. In contrast to that, the inclusive vector meson production at $\Delta \neq 0$ enables one to determine the full set of helicity-conserving and helicity-flip amplitudes and investigate the spin properties of hard (generalized) Compton scattering to full complexity.
Fig. 3. Schematic diagram of exclusive vector-meson production in *ep* interaction, $ep \longrightarrow eVp$.

1.3. When Vector Meson Production Is Dominated by Small Color Dipole Interactions?

The intimate relationship between inclusive DIS, DVCS, and exclusive vector meson production is still better seen in the light-cone color dipole picture of small-*x* DIS which illustrates nicely the interplay of the scattering mechanism and the (partonic) structure of particles. It is needless to recall the outstanding role of the photon–matter interactions in the conception and formation of the quantum mechanics and quantum field theory. In the early years of the nonrelativistic quantum mechanics, the photon had been regarded as structureless and the focus of the theory was on spectral lines, photoeffect, and the related phenomena. With the advent of the first quantum field theory—the quantum electrodynamics (QED), it has become clear that the fundamental transition

$$\gamma \Leftrightarrow e^+ e^- \qquad (4)$$

between bare particles gives rise to a concept of a dressed physical photon that contains all bare states to which it couples via (4) and still higher-order QED processes. At low energies, the virtual vacuum polarization gives rise to the well-known Uehling–Serber radiative correction to the Coulomb potential; at higher energies, the familiar Bethe–Heitler e^+e^- pair production in the Coulomb field of a nucleus can be viewed as materialization of the e^+e^- component of the physical photon (see Bjorken *et al.* [32]). The Compton scattering which is behind inclusive DIS at very small values of the Bjorken variable *x* can be viewed as (i) the transition of the virtual photon to the $q\bar{q}$ pair (the color dipole) at a large distance

$$l \sim \frac{1}{m_N x} \qquad (5)$$

upstream the target (here, m_N is the nucleon mass), (ii) interaction of the color dipole with the target nucleon, and (iii) the projection of the scattered $q\bar{q}$ onto the virtual photon (Fig. 4a). Notice the very special choice of the stage (iii): if one lets the scattered color dipole materialize as hadrons, one ends up with the large rapidity gap DIS—the diffractive excitation $\gamma^* p(P) \longrightarrow p(P')X$. Here, the production of continuum hadronic states X is modeled by the continuum $q\bar{q}$ states (Fig. 4b), whereas the projection of the scattered $q\bar{q}$ color dipole onto the vector meson gives the exclusive (diffractive, elastic) vector meson production, and projection onto the real photon gives so-called DVCS (Fig. 4c). The amplitude of the transition of the photon into the $q\bar{q}$ state, alias the $q\bar{q}$ wave function of the photon, and the amplitude of scattering the color dipole off the target are the universal ingredients in all the processes. The wave function of the virtual photon is well known [24], and different processes probe the color dipole scattering amplitude at different dipole sizes [18].

For instance, irrespective of the photon's virtuality Q^2, the inclusive diffractive DIS into the continuum states is controlled for the most part by interaction of large color dipoles [3]. The scaling violations in the proton structure function (SF), $\partial F_{2p}(x, Q^2)/\partial \log Q^2$, come from small color dipoles of size

$$r^2 \sim \frac{4}{Q^2 + 4m_q^2}, \qquad (6)$$

whereas the absolute value of $F_{2p}(x, Q^2)$ receives contributions from large to small dipole sizes [33, 34],

$$\frac{4}{Q^2 + 4m_q^2} < r^2 < \frac{1}{m_q^2}. \qquad (7)$$

Fig. 4. The unified picture of Compton scattering, diffraction excitation of the photon into hadronic continuum states and into the diffractive vector meson.
Fig. 5. The VDM amplitude for the vector meson photoproduction.

In contrast to the inclusive DIS and inclusive diffractive DIS, the amplitude of the exclusive vector meson production is dominated by the contribution from small dipoles of size [18, 19]

$$r \sim r_S \approx \frac{6}{\sqrt{Q^2 + m_V^2}} \qquad (8)$$

often referred to as the scanning radius (formula (8) is applicable only if r_S is smaller than the typical hadron size). Thus, exclusive vector meson production offers a cleaner environment for testing transition from soft to hard scattering.

The color dipole formalism is entirely equivalent to the BFKL formalism of the (transverse) momentum-dependent gluon distributions in the leading $\log(1/x)$ approximation [35–37]. Within this formalism, often referred to as the $k_\perp$-factorization, Eq. (8) suggests that the vector meson production probes the gluon density of the target at pQCD hard scale [19–22, 38]

$$\overline{Q}^2 \approx \frac{1}{4}(Q^2 + m_V^2) = \frac{9}{r_S^2}, \qquad (9)$$

which is large for heavy quarkonia (J/Ψ, Υ, ...) or for large Q^2. In the hard regime of small scanning radius, the vector meson production amplitudes will only depend on the wave function of vector mesons at a vanishing quark–antiquark separation in the two-dimensional transverse, or impact-parameter, space. There still remains a certain sensitivity to the separation of quarks in the longitudinal direction, which nonrelativistically is conjugate to the longitudinal Fermi motion of the quark and antiquark in the vector meson or the partition of the longitudinal momentum of the vector meson between the quark and antiquark in the relativistic light-cone language. As a result, the vector meson production amplitude is not calculable from the first principles of pQCD, still the sensitivity to the soft input can, to a large extent, be constrained by the decay $V \longrightarrow e^+e^-$, which proceeds via the short-distance annihilation $q\bar{q} \longrightarrow e^+e^-$. Then, Eq. (8) suggests that, upon factoring out the emerging $V \longrightarrow e^+e^-$ decay amplitude, the vector meson production amplitudes will depend on the hard scale $\overline{Q}$ in a universal manner. Finally, the energy dependence of the vector meson production

amplitude offers a more local probe of the properties of the hard pQCD Pomeron than the inclusive DIS.

1.4. The Scale for the Onset of Hard Regime

Before opening the issue of hard production of vector mesons, one needs to define the typical soft production. Here, a brief comment on the venerable vector dominance model (VDM) is in order. Because of the obvious dominance by the vector meson pole contribution, the point at $Q_f^2 = -m_V^2$, the amplitude of the production of the timelike virtual photon $\gamma^*(Q_f^2)$ will be proportional to the appropriate vector meson production amplitude times the $\gamma^*(-m_V^2)V$ transition amplitude is a tautology. Experimentally, the timelike photons are produced in the e^+e^- annihilation, and the $\gamma^*(-m_V^2)V$ transition amplitudes are measured at the e^+e^- colliders and, of course, in the decay $V_0 \longrightarrow e^+e^-$. The assumption that the ground-state vector meson pole contribution dominates the photoproduction amplitudes, and the $\gamma^*(Q_f^2)V$ transition amplitude does not vary substantially from the vector meson pole $Q_f^2 = -m_V^2$ down to $Q_f^2 = 0$ is the basis of the very successful VDM as formulated by Sakurai [39], Gell-Mann *et al.* [40, 41] (for the comprehensive review of foundations and tests of the VDM, see Bauer *et al.* [42]).

From the color dipole point of view, the success of the VDM in real photoproduction derives from the proximity of the distribution of color dipoles $q_f\bar{q}_f$ in the ground-state vector mesons and in the real photon. So, the $q_f\bar{q}_f$ component of the physical photon can be approximated by the corresponding vector meson (quarkonium), and the amplitude of interaction of the color dipole with the nucleon can be approximated by the vector meson–nucleon scattering amplitude (for an illustration, see Fig. 5). From the naive quark model viewpoint, the ρ-meson is the hyperfine partner of the π-meson and the two-dimensional charge radius, R_π, of the $\pi^\pm$ sets the relevant scale.

One comes to the same conclusion from the experimental observation that, to a very good accuracy, the t-dependence of elastic πN scattering, real Compton scattering $\gamma p \longrightarrow \gamma p$, and real photoproduction $\gamma p \longrightarrow \rho p$ is the same [42, 43]. Indeed, within the VDM, which is a very good approximation for real photons, the differential cross sections of the latter two processes are proportional to the differential cross section of elastic ρN scattering. Then, the equal t-dependence of the πN and ρN elastic scattering entails an equality of the radii of the ρ-meson.

Experimentally, the charge form factor of the pion is well described by the VDM ρ-pole formula and [44, 45]

$$\langle \mathbf{r}_\pi^2 \rangle^{1/2} \approx 0.55 \text{ fm} \approx \frac{2}{m_\rho}. \tag{10}$$

The onset of the hard regime in diffractive vector meson production requires that the scanning radius r_S is smaller than any other hadronic scale. First place, one needs $r_S^2 \ll \langle \mathbf{r}_\rho^2 \rangle \approx \langle \mathbf{r}_\pi^2 \rangle$, i.e.,

$$Q^2 \gg \frac{5}{4} m_\rho^2 \approx 1 \text{ GeV}^2. \tag{11}$$

The corrections in the small parameter $r_S / \langle \mathbf{r}_V^2 \rangle^{1/2}$ depend on the wave function (WF) of the vector meson. With the soft, Gaussian, wave function, $\psi_V(r) \sim \exp(-r^2/\langle \mathbf{r}_V^2 \rangle)$, in order for the WF-dependent corrections not to exceed $\lesssim 20$–30%, one needs $Q^2 \gtrsim 2$–4 GeV^2. For the hard, Coulomb-like, wave functions, $\psi_V(r) \sim \exp(-r/\langle \mathbf{r}_V^2 \rangle^{1/2})$, a still higher $Q^2 \gtrsim 10$ GeV^2 is needed for a similar insensitivity to the shape of the wave function (for a related discussion of the onset of pQCD, see [46]). Even for the heavy J/Ψ, the scanning radius at $Q^2 = 0$ is large,

$$r_s \approx \frac{6}{m_c} \sim \langle \mathbf{r}_{J/\Psi}^2 \rangle^{1/2} \approx 0.4 \text{ fm} \tag{12}$$

(for the charmonium parameters, see [47–49]), so that, for the onset of the short-distance regime insensitive to the shape of the wave function of the J/Ψ, one needs $Q^2 \gtrsim m_{J/\Psi}^2$. In the realistic QCD, there is still another scale—the propagation radius for perturbative gluons which is small, $R_c \approx 0.2$–0.3 fm (for the lattice QCD evaluations of R_c, see [50]; for the origin of R_c in the instanton models of QCD vacuum, see [51]; the analysis of heavy quarkonia decays is found in [52]). The color dipole cross section is of true pQCD origin only for dipoles $r \lesssim R_c$, i.e., the fully pQCD description of diffractive vector mesons requires $r_S \lesssim R_c$, i.e.,

$$Q^2 \gtrsim Q_{\text{pQCD}}^2 = \frac{36}{R_c^2} \approx 20\text{–}30 \text{ GeV}^2. \tag{13}$$

One must not be discouraged, though: the r-dependence of the dipole cross section does not change dramatically from the pure pQCD domain of $r \lesssim R_c$ to the nonperturbative domain of $r \gtrsim R_c$, and the fundamental concept of the scanning radius remains viable up to $r_s \lesssim 1$ fm (see also the discussion in Section 3.3.2).

The large momentum transfer, $|t| \gg 1$ GeV^2, is another way to probe the structure of the photon and vector meson at short distances, $r \sim 1/\sqrt{|t|} \gg 1$ GeV^{-1}. It is generally believed [46, 53] that $|t|$ supersedes $\overline{Q}^2$ as a hard scale if $|t| \gtrsim \overline{Q}^2$. The caveats of t as large scale and of single BFKL Pomeron exchange dominance will be discussed to more detail in Section 4.11.

1.5. The Structure of the Review

In this review, we focus on the onset of hard pQCD regime in exclusive vector meson production at HERA. The presentation of the experimental data and of theoretical ideas goes in parallel, and an intimate connection between the vector meson production and the inclusive DIS will be repeatedly underlined. For this reason, the presentation of the theoretical ideas on vector meson production will be heavily biased towards the color dipole picture and its momentum-space counterpart—the so-called $k_\perp$-factorization.

The brief description of the H1 and ZEUS detectors, the kinematics of DIS and of the vector meson production, the event selection, the definition of major observables and of the spin density matrix of virtual photons is presented in Section 2. The subject of Section 3 is an overview of basic theoretical ideas on the vector meson production. Here, we discuss briefly the Regge theory of the soft photon and hadron interactions, the QCD approach to the vacuum exchange (the Pomeron), the flavor dependence, the connection between the vector meson production and the leptonic decay of vector mesons, the origin of s-channel helicity nonconservation (SCHNC), and the exclusive–inclusive duality connection between inclusive diffractive DIS and vector meson production. We also introduce the color dipole approach to DIS and vector meson production and explain how the shrinkage of virtual photons makes the vector meson production pQCD tractable. The unified microscopic QCD approach to small-x DIS and diffractive vector meson production—the $k_\perp$-factorization approach, which is equivalent to the color dipole approach—is presented in more detail in Section 4. Here, we discuss both the small-t production within the diffraction cone and major ideas on large-t proton dissociative reaction. This section can be skipped in the first reading but is essential for understanding the status of theoretical calculations of the vector meson production.

In Section 5, we start the presentation of the physics results with the helicity structure of the vector meson production. This includes the definition of the spin observables, an introduction into the important subject of the s-channel helicity nonconservation (SCHNC), and the comparison of the experimental data on the spin density matrix of produced vector mesons with the theoretical expectations from the color-dipole/$k_\perp$-factorization approach.[1] In Section 6, we discuss the Q^2-dependence of the vector meson production cross sections, as well as the longitudinal-to-transverse cross-section ratios $R_V = \sigma_L/\sigma_T$. We put special emphasis on the flavor dependence of cross sections, emphasize an importance of $(Q^2 + m_V^2)$ as the hard pQCD scale, and

---

[1] Throughout this review, the numerical results shown for the $k_\perp$-factorization are either taken from the PhD thesis [54] or performed specially for this review [55].

Table 1. HERA parameters

HERA parameters	Design	2000	Design after upgrade
p/e beam energy, GeV	820/30	920/27.5	920/30
p/e beam current, mA	160/58	>100/>50	140/58
Number of bunches proton/electron	210	180/189	180/189
Time between crossings, ns		96	
Proton β-function x/y, m;	10/1	7/0.5	2.45/0.18
Electron β-function x/y, m	2/0.7	1/0.7	0.63/0.26
Specific luminosity, cm^{-2} s^{-1} mA^{-2}	3.4×10^{29}	8×10^{29}	1.6×10^{30}
Luminosity, cm^{-2} s^{-1}	1.5×10^{31}	2×10^{31}	7×10^{31}

comment on the sensitivity of $R_V = \sigma_L/\sigma_T$ to the short-distance wave function of vector mesons. In Section 7, we review the experimental data on the energy dependence of the cross sections and its theoretical interpretation in terms of the Pomeron exchange. We show how the change of the energy dependence from light to heavy flavors and from photoproduction to DIS is controlled by $(Q^2 + m_V^2)$ as the hard pQCD scale. We comment on tricky points in comparison of hard scales and energy dependence in inclusive DIS and diffractive vector meson production and on the impact of the interplay of the scanning radius r_S and the position of the node of the radial wave function for the $\Psi(2S)$ production cross section. The focus of Section 8 is on the t-dependence of the cross sections, both in the low-t and high-t regimes. The discussion of low-t data centers on the Q^2, m_V, and W-dependence of the diffraction cone slope. The recurrent theme is a universality of diffraction slopes as a function of the scanning radius and/or $(Q^2 + m_V^2)$ as the hard pQCD scale. The properties of the Pomeron trajectory $\alpha_P(t)$ extracted from the vector meson production data are discussed in detail: the experimentally observed shrinkage of the diffraction cone for the J/Ψ production gives strong evidence for $\alpha_P(t)$ which decreases with t approximately linearly at $|t| \lesssim 1$ GeV^2 but then starts rising up to $\alpha_P(t) \sim 1.3$ in the hard regime of large $|t|$. Finally, in Section 9, we summarize the principal findings from HERA experiments on diffractive vector meson production and list open issues in the pQCD interpretation of these data.

It is important to mention here that not all of the currently available HERA data are always shown in each plot where they may belong. This is because, sometimes, the published plots from H1, ZEUS, and other authors are used without any modifications. This is especially valid for the "preliminary" H1 and ZEUS plots that have been shown to the conferences and are not yet submitted in form of "official" papers. Such plots are just taken as they are. If, for some compilation and figures, only very recent data are used, it is explained in the correspondent caption.

2. THE EXPERIMENTAL OVERVIEW

2.1. HERA

HERA (hadron electron ring anlage) is the world's first lepton–proton collider located at Deutsches Elektronen Synchrotron (DESY) site in Hamburg, Germany (see, e.g., [56] and references therein). The HERA ring has a circumference of about 6.3 km with two separated synchrotron rings for electrons (positrons) and protons. It runs 10–30 m below ground level and has four experimental areas. In two of them, the beams are made to collide to provide *ep* interactions for the H1 and ZEUS experiments. The remaining two areas are used by the fixed-target experiments: HERMES [57], which scatters longitudinally polarized electrons off stationary polarized targets, and HERA-B [58, 59], which investigated *CP*-violation in the $B^0\bar{B}^0$ system by scattering beam halo protons off wire targets (was shut down in 2000). HERA was commissioned in 1991 with the first *ep* collision observed by H1 and ZEUS in the spring 1992. A major HERA upgrade took place during the 2000–2002 break. A significant luminosity increase should be achieved by stronger focusing of both the electron and the proton beams (see Table 1, where the design and achieved HERA values, as well the values of HERA after upgrade, are summarized). Further information about HERA luminosity upgrade can be found in [60, 61].

2.2. The H1 and ZEUS Detectors

The H1 and ZEUS are general-purpose detectors with nearly hermetic calorimetric coverage and a large forward–backward asymmetry to accommodate the boost of the *ep* center of mass in the direction of the proton beam.

The H1 and ZEUS detectors are described in detail elsewhere [62, 63]. The detectors are shown in Figs. 6 and 7. The main difference between the H1 and ZEUS detectors is the choice of the calorimetry. In the H1 case, the main liquid argon calorimeter with different tracking detectors inside is surrounded by a large-diameter superconducting solenoid, thus minimizing the amount of inactive material in the path of the particles
HERA Experiment H1

Fig. 6. The H1 detector. The main components are: 1, 7, 11—beam, compensating, and muon toroid magnets; 2—central tracking detector; 3—forward tracking and transition radiators; 4, 5—liquid argon calorimeter; 6—superconducting coil; 9—muon chambers; 12, 13—warm electromagnetic and plug calorimeters.

between the interaction point and the calorimeter. In the ZEUS case, only tracking chambers are placed inside a superconducting solenoidal magnet, surrounded by a uranium-scintillator sampling calorimeter with equal response to the electromagnetic and hadronic components. Both detectors are surrounded by muon chambers. Some of the components most relevant for the vector meson analysis are outlined below.

2.2.1. Tracking detectors. Charged particles are measured both for H1 and ZEUS by the central tracking detectors operating in magnetic field of 1.15 and 1.43 T, respectively. Both trackers are built mainly of drift, jet, and proportional chambers. The part closest to the

beam pipe in H1 case uses silicon detectors (central silicon tracker). During the 2000–2001 shutdown, ZEUS also installed a silicon microvertex detector that should significantly improve the resolution of the tracking system and the vertex reconstruction.

The polar angle coverage is $15° < \theta < 164°$ (165°) for H1 (ZEUS), correspondingly. The relative transverse-momentum resolution is $\sigma(p_T)/p_T \approx 0.006 p_T$ with p_T in GeV for both experiments. Charged particles in the forward direction are detected in the forward tracking detector covering the polar angle range $7° < \theta < 25°$ and $7° < \theta < 28°$ for the H1 and ZEUS, respectively; the backward part ($172° < \theta < 176°$) is covered by the back-

Overview of the ZEUS Detector
(longitudinal cut)

Fig. 7. The ZEUS detector. The main components are: *VXD*—vertex detector, after 2000 upgrade silicon microvertex detector; *CTD*—central tracking detector; *FDET*—forward detector; *RTD*—rear tracking detector; *F/RMUON*—forward/rear muon chambers; *BMUOI/O*—barrel muon inner/outer chambers; *F/B/RCAL*—forward/barrel/real calorimeters; *BAC*—backing calorimeter.

ward silicon tracker, BST in the H1, and by the small rear tracking detector in the ZEUS cases.

Charged tracks measured by the tracking system are used to reconstruct the interaction vertex for each event.

2.2.2. Calorimetry. The tracking detectors of H1 are surrounded by a liquid argon calorimeter (LAr, $4° < \theta < 154°$, σ/E: $0.12/\sqrt{E}$ and $0.50/\sqrt{E}$ for electromagnetic and hadronic showers correspondingly, E in GeV) and a scintillating fiber calorimeter (spaghetti calorimeter, SpaCal, $153° < \theta < 178°$, $0.075/\sqrt{E}$ for electromagnetic showers).

The central tracking detector of ZEUS is placed inside of a thin superconducting coil. Surrounding the solenoid is the high-resolution uranium-scintillator calorimeter (CAL) which covers the angular range $2.6° < \theta < 176.2°$ with equal response to the electromagnetic and hadronic components and with energy resolution of $0.18/\sqrt{E}$ and $0.35/\sqrt{E}$ for the electromagnetic and hadronic components, correspondingly.

In 1998–2000, a forward plug calorimeter (FPC, lead-scintillator sandwich calorimeter [64]) was installed in the 20×20 cm^2 beam hole of the forward part of the CAL with only a small hole of radius 3.15 cm in the center to accommodate the beam pipe. It extended the pseudo-rapidity coverage of the forward calorimeter from $\eta < 4.0$ to $\eta < 5.0$. A similar device—beam pipe calorimeter (BPC)—was installed in the rear region of the ZEUS detector, 294 cm away from the nominal *ep* interaction point, mainly to measure the lepton scattered at a very small angle. Both these calorimeters were removed during the 2000–2001 shutdown because of the changed beam-pipe geometry for the HERA luminosity upgrade.

2.2.3. Muon detectors. The H1 muon system consists of an instrumented iron return yoke (central muon detector (CMD), $4° < \theta < 171°$) and a forward muon detector (FMD, $3° < \theta < 17°$).

The ZEUS muon system covers the polar angles between $10° < \theta < 171°$; in addition, the forward part has additional drift chambers for high-momentum muon reconstruction for polar angles between $6°$ and $30°$.

2.2.4. Forward detectors and proton taggers. Both H1 and ZEUS have very forward detectors, placed along the beam line in the direction of the proton beam, 20–90 m away from the nominal interaction point.

Forward proton spectrometer (FPS in H1) and leading proton spectrometer (LPS in ZEUS) consist of movable "Roman Pots" forming together with the magnets of HERA a kind of magnetic spectrometer. Scattered protons with a different energy and/or angle compared to the nominal beam protons are separated from the beam and are detected at appropriate positions.

Also in the proton direction experiments have placed simple scintillation counters (5.15 and 23–24 m from the nominal interaction point in the ZEUS case, five stations between 9 and 92 m in the H1 case) that are

used as proton remnant taggers (PRT). These taggers cover very high region of pseudorapidity (e.g., $4.3 < \eta < 5.8$ for ZEUS) and are used to tag the events where the proton dissociate.

2.2.5. Luminosity detectors and electron taggers. The luminosity is determined from the rate of the Bethe–Heitler bremsstrahlung process $ep \longrightarrow e\gamma p$, where the high-energy photon is detected in a lead-scintillator calorimeter (LUMI) located at $Z = -107$ m in the HERA tunnel in the ZEUS case or by a crystal Cherenkov calorimeter (PD) located at $Z = -103$ m in the H1 case.

In the lepton direction, the experiments have photo-production taggers (PT) at 8 and 44 m from the nominal interaction point for ZEUS, electron taggers (ET) in the H1 case. They detect leptons scattered under a very small angle (less than few mrad). The leptons measured in the PT (ET) are used to tag photoproduction events, thus significantly reducing the background.

2.3. Kinematics and Cross Sections

2.3.1. Kinematics of DIS. Because of the small electromagnetic coupling $\alpha_{em} \approx 1/137$, the deep inelastic scattering of leptons off protons is treated in the one-photon exchange approximation. The generic diagram for DIS $e(k)p(P) \longrightarrow e(k')X$ is shown in Fig. 1. The relevant kinematic variables are:

$Q^2 = -q^2 = -(k - k')^2$, the negative squared four-momentum of the virtual photon;

$W^2 = (q + P)^2 = 2m_p\nu + m_p^2 - Q^2$, the squared center-of-mass energy of the photon–proton system;

$y = (Pq)/(Pk)$, the fraction of the positron energy transferred to the photon in the proton rest frame;

$x = Q^2/2(Pq)$, the Bjorken variable, which in the parton model interpretation of DIS has a meaning of the fraction of the proton's light-cone momentum carried by the struck charged parton.

2.3.2. The flux and polarization of photons. The amplitude of DIS equals

$$T(e(k)p(P) \longrightarrow e(k')X)$$
$$= \frac{4\pi\alpha_{em}}{Q^2}\langle e(k')|l_\mu|e(k)\rangle g_{\mu\nu}\langle X|J_\nu|p(P)\rangle, \quad (14)$$

where l_μ and J_μ stand for the electromagnetic current of leptons and hadrons. The leptons serve as a source of photons, and the physical process is the virtual photo-absorption

$$\gamma^*(q)p(P) \longrightarrow X.$$

The virtual photons have three polarization states: the two spacelike transverse ones with helicities $\lambda_{\gamma^*} = \pm 1$,

$$\mathbf{e}(\pm) = -\frac{1}{\sqrt{2}}(\pm\mathbf{e}_x + i\mathbf{e}_y)e^{\pm i\Phi} \quad (15)$$

and the timelike *scalar* state (often misnamed the *longitudinal* one; hereafter, we follow this tradition)

$$e_\mu(L) = -\sqrt{\frac{Q^2}{(Pq)^2 + P^2Q^2}}\Big[P_\mu + \frac{(Pq)}{Q^2}q_\mu\Big].$$

For the purpose of future convenience, here, we choose the z-axis along the photon's 3-momentum, the x-axis in the $\gamma p \longrightarrow Vp$ reaction plane, and Φ is the azimuthal angle between the reaction and the (e, e') scattering planes (for more details, see Section 5.1 below). The complete set includes still another spacelike vector

$$e_\mu(S) = \frac{1}{\sqrt{Q^2}}q_\mu.$$

Making use of the expansion

$$g_{\mu\nu} = e_\mu^*(L)e_\nu(L) - \mathbf{e}_\mu^*(+)\mathbf{e}_\nu(+)$$
$$- \mathbf{e}_\mu^*(-)\mathbf{e}_\nu(-) - e_\mu^*(S)e_\nu(S)$$

and of the current conservation, $(e(S)J) = 0$, one can write down

$$\langle e(k')|l_\mu|e(k)\rangle g_{\mu\nu}\langle X|J_\nu|p(P)\rangle$$
$$= \langle e(k')|l_\mu|e(k)\rangle e_\mu^*(L)\langle X|J_\nu|p(P)\rangle e_\nu(L)$$
$$- \langle e(k')|l_\mu|e(k)\rangle \mathbf{e}_\mu^*(+)\langle X|J_\nu|p(P)\rangle \mathbf{e}_\nu(+) \quad (16)$$
$$- \langle e(k')|l_\mu|e(k)\rangle \mathbf{e}_\mu^*(-)\langle X|J_\nu|p(P)\rangle \mathbf{e}_\nu(-).$$

Now, notice that

$$T(\gamma^*(\lambda_{\gamma^*}; q)p(P) \longrightarrow X)$$
$$= \sqrt{4\pi\alpha_{em}}\langle X|J_\nu|p(P)\rangle e_\nu(\lambda_{\gamma^*}) \quad (17)$$

is precisely an amplitude of the photoabsorption for the photon of polarization λ_{γ^*}, and $\langle e(k')|l_\mu|e(k)\rangle e_\mu^*(L)$, $-\langle e(k')|l_\mu|e(k)\rangle e_\mu^*(+)$, $-\langle e(k')|l_\mu|e(k)\rangle e_\mu^*(-)$ define the emission by leptons of photons of appropriate polarization, which is quantified by the spin density matrix of the photon $\rho_{\lambda'\lambda}$. Then, making use of the expansion (16), the differential cross section for the lepto-production of the specific final state X can be expressed through the photoabsorption cross sections as

$$\frac{d\sigma(ep \longrightarrow e'X)}{dQ^2 dy}d\tau_X$$
$$= \Gamma_T(Q^2, y) \sum_{\lambda', \lambda = +, -, L} \rho_{\lambda'\lambda}d\sigma_{\lambda'\lambda}(\gamma^* p \longrightarrow X), \quad (18)$$

where $d\tau_X$ is the element of the appropriate phase space,

$$d\sigma_{\lambda'\lambda}(\gamma^* p \longrightarrow X) = \frac{1}{4\sqrt{(pq)^2 + Q^2 m_p^2}} \quad (19)$$
$$\times \mathcal{T}^*(\gamma_{\lambda'}^* p \longrightarrow X)\mathcal{T}(\gamma_\lambda^* p \longrightarrow X)d\tau_X,$$

and

$$\Gamma_T(Q^2, y) = \frac{\alpha_{em}}{\pi Q^2 y}\left(1 - y + \frac{1}{2}y^2\right) \qquad (20)$$

is the flux of transverse photons. With this normalization, the spin density matrix of the photon equals

$$\begin{pmatrix} \rho_{++} & \rho_{+-} & \rho_{+L} \\ \rho_{-+} & \rho_{--} & \rho_{-L} \\ \rho_{L+} & \rho_{L-} & \rho_{LL} \end{pmatrix} \qquad (21)$$

$$= \begin{pmatrix} \dfrac{1}{2} & -\dfrac{1}{2}\epsilon e^{2i\Phi} & \dfrac{1}{2}\sqrt{\epsilon(1+\epsilon)}\,e^{i\Phi} \\[2mm] -\dfrac{1}{2}\epsilon e^{-2i\Phi} & \dfrac{1}{2} & -\dfrac{1}{2}\sqrt{\epsilon(1+\epsilon)}\,e^{-i\Phi} \\[2mm] \dfrac{1}{2}\sqrt{\epsilon(1+\epsilon)}\,e^{-i\Phi} & -\dfrac{1}{2}\sqrt{\epsilon(1+\epsilon)}\,e^{i\Phi} & \epsilon \end{pmatrix},$$

where

$$\epsilon = \frac{1 - y - y^2\dfrac{Q^2}{4\nu^2}}{1 - y + \dfrac{1}{2}y^2 + y^2\dfrac{Q^2}{4\nu^2}} \approx \frac{2(1-y)}{(1-y)^2 + 1} \qquad (22)$$

is the longitudinal polarization of the virtual photon. We also indicated the small-x approximation for ϵ which is appropriate for DIS at HERA.

Notice that, because of the current conservation, one can define the longitudinal photon interaction amplitude in terms of the current component J_z, which is customary in electronuclear physics (for instance, see [65–67]). It does not affect the observed cross section (18), because the different normalization of the amplitude (16) for longitudinal photons is compensated for by the change of the relevant components of the spin-density matrix of the photon.

2.3.3. The transverse and longitudinal cross sections for DIS. In the fully inclusive DIS, one integrates over the whole phase space of the state X and sums over all states X. Then, by virtue of the optical theorem, one can relate the photoabsorption cross section to the absorptive part of the Compton forward scattering amplitude

$$\sum_X \sigma_{\lambda'\lambda}(\gamma^* p \longrightarrow X)$$

$$= \frac{1}{2\sqrt{(pq)^2 + Q^2 m_p^2}} \mathrm{Im}\,\mathcal{T}_{\lambda'\lambda}(\gamma^* p \longrightarrow \gamma^* p). \qquad (23)$$

The crucial point is that, for the unpolarized target, the helicity-flip, $\lambda' \neq \lambda$, amplitudes vanish in the forward scattering. Then, the virtual photon–proton cross section, $\sigma^{\gamma^* p}$, can be determined from the measured positron–proton cross section:

$$\sigma^{\gamma^* p} = \sigma_T^{\gamma^* p} + \epsilon\sigma_L^{\gamma^* p} = \frac{1}{\Gamma_T(Q^2, y)}\frac{d^2\sigma^{ep}}{dQ^2 dy}, \qquad (24)$$

where $\sigma_T^{\gamma^* p} = \sigma_{++} = \sigma_{--}$ and $\sigma_L^{\gamma^* p}$ are the transverse and the longitudinal virtual photoproduction cross sections, respectively. The often discussed total inclusive cross section, $\sigma_{\mathrm{tot}}^{\gamma^* p} = \sigma_T^{\gamma^* p} + \sigma_L^{\gamma^* p}$, can be determined from $\sigma^{\gamma^* p}$ through the relation

$$\sigma_{\mathrm{tot}}^{\gamma^* p} = \frac{1 + R_{\mathrm{DIS}}}{1 + \epsilon R_{\mathrm{DIS}}}\sigma^{\gamma^* p}, \qquad (25)$$

where

$$R_{\mathrm{DIS}} = \frac{\sigma_L^{\gamma^* p}}{\sigma_T^{\gamma^* p}}. \qquad (26)$$

(Because R is heavily used for different ratios, we supply it by the subscript DIS.) In the kinematic range of most of the discussed measurements, the value of ϵ is close to unity, and because R_{DIS} is small, $\sigma^{\gamma^* p}$ differs from $\sigma_{\mathrm{tot}}^{\gamma^* p}$ by less than 1%.

2.4. Kinematics of Diffractive Vector Meson Production

Diffractive vector meson production corresponds to the special two-body final state, which contains only the vector meson and scattered proton

$$e(k)p(P) \longrightarrow e(k')V(v)p(P'),$$

where $V = \{\omega, \rho, \phi, J/\psi, \Psi', \Upsilon\}$ and k, k', P, P', and v are the four-momenta of the incident lepton (positron or electron), scattered lepton, incident proton, scattered proton, and vector meson, respectively (see Fig. 3).

The new kinematic variable is $t = (P - P')^2 = (v - q)^2 = -\Delta^2 + t_{\mathrm{min}}$, the squared four-momentum transfer at the proton vertex. At high energies, the longitudinal momentum transfer $\Delta_L = m_p(Q^2 + m_V^2)/W^2$ is small, $t_{\mathrm{min}} = -\Delta_L^2$ can be neglected, and $t \approx t' \equiv -\Delta^2$. Besides t, the new important variables are the orientation of the production plane with respect to the electron scattering plane and the appropriately defined polar and azimuthal angles of the decay pions, which will be discussed in Section 5.

The major background process is the proton-dissociative reaction $ep \longrightarrow eVY$, and, in addition to the above quantities, M_Y, the mass of the diffractive excitation of the proton is used.

2.5. The Event Reconstruction

For the photoproduction events, $Q^2 \approx 0$, Q^2 ranged from the kinematic minimum, $Q_{\mathrm{min}}^2 = M_e^2 y^2/(1 - y) \approx$

Table 2. The recent H1 and ZEUS photoproduction measurements discussed throughout this paper. An overview of older data can be found in [10]. Information that is not available is labeled by n.d. The determination of the diffraction slope is based on the data at $|t| \lesssim 1$ GeV^2

10^{-12} GeV^2, where M_e is the positron mass, up to $Q^2_{\max} \approx 1$ GeV^2, the value at which the scattered positron starts to be observed in the calorimeter, with a median Q^2 of approximately 5×10^{-5} GeV^2 (differs slightly for ZEUS and H1 and from year to year with modifications in calorimeter geometry). Since the typical Q^2 is small, it can be neglected in the reconstruction of the other kinematic variables.

For the DIS events, the kinematic variables are reconstructed using the momenta of the decay particles and the polar and azimuthal angles of the measured scattered lepton. Neglecting the transverse momentum of the outgoing proton with respect to its incoming momentum, the energy of the scattered positron can be expressed as

$$E_{e'} \simeq [2E_e - (E_V - p_V^Z)]/(1 - \cos\theta_{e'}),$$

where E_e is the energy of the incident lepton, E_V and p_V^Z are the energy and longitudinal momentum of the vector meson V, and $\theta_{e'}$ is the polar angle of the scattered lepton. The value of Q^2 was calculated from

$$Q^2 = 2E_{e'}E_e(1 + \cos\theta_{e'}).$$

The photon–proton center-of-mass energy, W, can be expressed as $W^2 \approx 2E_p(E - p_Z)_V + Q^2$, where E_p is the laboratory energy of the incoming proton and $(E - p_Z)_V$

is the difference between the energy and the longitudinal momentum of the vector meson. The fraction of the positron momentum carried by the photon is calculated from $y = (E - p_Z)_V/2E_e$.

The squared four-momentum transfer at the proton vertex is given by $|t| = (p_{e'} + p_V)_X^2 + (p_{e'} + p_V)_Y^2$.

2.6. Data Samples and Event Selection

The kinematic region for each particular data sample can be found in Tables 2 and 3. The tables summarize all the recent data discussed in this paper (for the overview of the pre-1997 experimental data, see [10]).

3. AN OVERVIEW OF THEORETICAL APPROACHES TO DIFFRACTIVE SCATTERING

3.1. The Rudiments of the Regge Theory of Strong Interactions

As Bjorken emphasized, the foundations of the Regge theory are as solid as QCD itself [91]. Because the physics of diffractive scattering is permeated by ideas and concepts from the Regge theory of strong interactions, a brief introduction of this subject is in order. For the more rigorous treatment and for technicalities, one must consult the textbooks [12, 13, 92], the review papers [93–95], and the collection of reprints [96].

Table 3. The recent H1 and ZEUS electroproduction measurements discussed throughout this paper. Overview of older data can be found in [10]. Notation is the same as in Table 2

3.1.1. The s-channel asymptotics from the t-channel exchanges: spin and energy dependence. There is a deep connection between the high-energy behavior of a binary reaction $ab \longrightarrow cd$ and the spin, J, of the *elementary* particle with mass M exchanged in the t-channel:

$$A_{ab \to cd}(W^2, t) = \frac{g_{ac}(t)g_{bd}(t)}{t - M^2}(W^2)^J, \quad (27)$$

$$\frac{d\sigma(ab \longrightarrow cd)}{dt} \propto \frac{g_{ac}^2(t)g_{bd}^2(t)}{(t - M^2)^2}W^{4(J-1)}. \quad (28)$$

Although it follows in a straightforward manner from the analysis of Feynman diagrams, it is instructive to look at (27) from the t-channel point of view. In the crossed channel

$$a\bar{c} \longrightarrow \bar{b}d$$

the total cms energy squared is $t = (p_a + p_{\bar{c}})^2 = (p_a - p_c)^2 = M^2$, the momentum transfer squared is $(p_a - p_{\bar{b}})^2 = s = (p_a + p_b)^2$, and the exchanged particle emerges as a resonance at $t = M^2$ in the partial wave J. The angular dependence of this contribution to the scattering amplitude is given entirely by the Legendre polynomial

$$A_{ab \to cd}^{\sigma_t}(W^2, t) = A_J(t)P_J(\cos\theta_t)$$
$$= \frac{G_{a\bar{c}}(t)G_{\bar{b}d}(t)}{t - M^2}[\sigma_t + (-1)^J]P_J(-\cos\theta_t), \quad (29)$$

where (for the sake of simplicity, we take $m_a = m_b = m_c = m_d = \mu$)

$$\cos\theta_t = 1 + \frac{2W^2}{t - 4\mu^2}. \quad (30)$$

The so-called signature $\sigma_t = \pm 1$ separates the crossing-even and crossing-odd amplitudes; for instance, in the crossing-even $\pi^0\pi^0$ scattering, $\sigma_t = +1$ and the contribution from the odd-partial waves to (29) vanishes identically.

The amplitude (29) depends on W^2 only through the Legendre polynomial and can readily be continued analytically into the high-energy domain of $W^2 \gg M^2$, μ^2, $|t|$, which amounts to $-\cos\theta_t \gg 1$ and $P_J(-\cos\theta_t) \propto (-\cos\theta_t)^J \propto (W^2)^J$, i.e., we derived the asymptotics (27) by analytic continuation from the t-channel to s-channel scattering.

3.1.2. The regge trajectories. On the one hand, the existence of high-spin resonances is an ultimate truth of the physics of strong interactions; on the other hand, the exchange by an elementary particles of spin $J > 1$ would conflict the fundamental Froissart bound [97]:

$$A(W^2, t) < W^2 \log^2 W. \tag{31}$$

The sole known way out of this trouble is offered by the Regge theory: One must improve upon the above mock-up analytic continuation going from the sum over integer (or half integer) partial waves to the Sommerfeld–Watson integral over the complex angular momentum J with which the analytic continuation to $-\cos\theta_t \gg 1$ must be complemented with the appropriate deformation of the integration contour on the complex-J plane [98]. The key point is that the asymptotic behavior of the s-channel amplitude will be controlled by singularities of the partial wave $A_J(t)$ in the complex-J plane. If the singularity is the (Regge) pole,

$$A_J(t) \propto \frac{1}{J - \alpha_R(t)}, \tag{32}$$

then one obtains precisely the amplitude of the form (27) with $J = \alpha_R(t)$. The t-channel unitarity dictates [98, 99] that the Regge pole must be a moving one; i.e., it must have a finite slope $\alpha'_R(t)$. Experimentally, the Regge trajectory $\alpha_R(t)$ for the s-channel scattering at $t < 0$ can be extracted from the energy dependence of the differential cross sections and can be linked to the resonance mass spectrum by extrapolation of the mass dependence of the spin of t-channel resonances, $J_n = \alpha_R(M_n^2)$. Such Chew–Frautschi plots are well approximated by straight lines,

$$\alpha_R(M_n^2) \approx \alpha_R(0) + \alpha'_R t. \tag{33}$$

For instance, for the ρ, ω, A_2, f_2 families of resonances with nonvacuum quantum numbers, such extrapolations suggest the intercept $\alpha_R(0) \approx 0.45$, in very good agreement with the results from the scattering experiments. To cite a few examples, the ρ-trajectory is best studied in the charge-exchange $\pi^- p \longrightarrow \pi^0 n$, the A_2-trajectory is probed in $\pi^- p \longrightarrow \eta n$, the ω-trajectory is probed in the regeneration $K_L \longrightarrow K_S$ on the isoscalar target, the π-trajectory is probed in the charge-exchange $np \longrightarrow pn$, etc. (For classic reviews on the Regge trajectories, see [95]; a more recent discussion of the Chew–Frautschi plots is found in [100].) The high-lying Pomeron, ρ, ω, A_2, f_2 are the natural spin–parity exchanges; i.e., the spin J and parity P of particles lying on the corresponding Regge trajectory are related by $P = (-1)^J$. The unnatural spin–parity π, A_1 exchanges, $P = -(-1)^J$, have much lower intercepts, $\alpha_\pi(0) \approx \alpha_{A_1}(0) \approx 0$.

3.1.3. The universality aspects of the regge exchange. The ansatz (27) bears all the salient features of the realistic Reggeon-exchange amplitude:

(1) The trajectory $J = \alpha_R(t)$ is universal for all beam and target particles; it only depends on the t-channel quantum numbers.

(2) Dependence on the initial- and final-state particles has a factorized form.

(3) If one parametrizes the t-dependence of the near-forward differential cross section by the so-called slope parameter B,

$$\frac{d\sigma}{dt} \propto \exp(-B|t|), \tag{34}$$

then the factorization property entails

$$B(ab \longrightarrow cd) = B_{ac} + B_{bd} + B_R, \tag{35}$$

where B_{ac} and B_{bd} come from the form factors of the $a \longrightarrow c$ and $b \longrightarrow d$ transitions, and B_R characterizes the exchanged Reggeon.

(4) Notice that

$$\begin{aligned}
(W^2)^{\alpha_R(t)} &= (W^2)^{\alpha_R(0)} (W^2)^{\alpha'_R t} \\
&= (W^2)^{\alpha_R(0)} \exp[-\alpha'_R|t|\log(W^2)],
\end{aligned} \tag{36}$$

what entails Gribov's growth of the slope parameter with energy, alias the shrinkage of the diffraction cone [99]:

$$B_R = 2\alpha'_R \log\left(\frac{W^2}{s_0}\right). \tag{37}$$

The slope of all the nonvacuum Regge trajectories is about the same,

$$\alpha'_R \approx \frac{1}{2m_\rho^2} \approx 0.9 \text{ GeV}^{-2} \tag{38}$$

(for the recent summary, see [100]).

(5) The phase of the Reggeon exchange amplitude is uniquely fixed by the analytic continuation of the signature factor $\eta(\sigma_t, t) = \sigma_t + (-1)^{\alpha_R(t)} = \sigma_t - \exp[-i\pi(\alpha_R(t)-1)]$:

$$\frac{\operatorname{Re} A(W^2, t)}{\operatorname{Im} A(W^2, t)} = \begin{cases} \tan\left[\dfrac{\pi}{2}(\alpha_R(t)-1)\right], & \text{if} \quad \sigma_t = +1 \\[2ex] \cot\left[\dfrac{\pi}{2}(\alpha_R(t)-1)\right], & \text{if} \quad \sigma_t = -1. \end{cases} \tag{39}$$

3.1.4. The vacuum exchange: the pomeron trajectory from hadronic scattering. Elastic scattering is driven via unitarity by strongly absorptive inelastic multiproduction processes, which is nicely illustrated by the impact parameter representation—the high-energy version of the partial wave expansion. In high-energy elastic scattering, the momentum transfer, $\boldsymbol{\Delta}$, is the two-dimensional vector transverse to the beam momentum. The elastic scattering amplitude can be cast in the form of the Fourier transform

$$\frac{1}{W^2} A(W^2, \boldsymbol{\Delta}) = 2i \int d^2\mathbf{b}[1 - S(\mathbf{b})]\exp(-i\mathbf{b}\boldsymbol{\Delta}), \tag{40}$$

where $S(\mathbf{b}) = \exp(2i\delta(\mathbf{b}))$ is the S-matrix for elastic scattering at an impact parameter $\mathbf{b}$ and the angular momentum $l = |\mathbf{p}| \cdot |\mathbf{b}|$. The total elastic and inelastic cross sections equal

$$\sigma_{\text{el}} = \int d^2\mathbf{b}|1 - S(\mathbf{b})|^2,$$

$$\sigma_{\text{in}} = \int d^2\mathbf{b}[1 - |S(\mathbf{b})|^2]. \qquad (41)$$

Strong absorption implies the predominantly imaginary scattering phase. One often uses the so-called profile function $\Gamma(\mathbf{b}) = 1 - S(\mathbf{b})$. The small momentum transfer expansion in (40) gives

$$\frac{1}{W^2}A(W^2, \Delta) = 2i\int d^2\mathbf{b}\Gamma(\mathbf{b})\left[1 - \frac{1}{2}(\mathbf{b}\Delta)^2\right]$$

$$= \frac{1}{W^2}A(W^2, 0)\left(1 - \frac{1}{2}B\Delta^2\right), \qquad (42)$$

so that the diffraction slope B is determined by the mean impact parameter squared:

$$B = \frac{1}{2}\langle\mathbf{b}^2\rangle = \frac{1}{2}\frac{\int d^2\mathbf{b}\,\mathbf{b}^2\Gamma(\mathbf{b})}{\int d^2\mathbf{b}\Gamma(\mathbf{b})}. \qquad (43)$$

The extreme case is the scattering on the absorbing black disc of radius R for which $|S(\mathbf{b})| = \theta(R - |\mathbf{b}|)$, which is a good approximation for the scattering of nucleons off heavy nuclei. Then,

$$\sigma_{\text{el}} = \sigma_{\text{in}} = \frac{1}{2}\sigma_{\text{tot}} = \pi R^2, \qquad (44)$$

and the diffraction slope equals

$$B_{\text{el}} = \frac{1}{4}R^2. \qquad (45)$$

Such a flat, energy-independent, elastic scattering must be contrasted to the two-body reactions with the nonvacuum exchange, which constitute a tiny fraction of high-energy inelastic collisions of hadrons and have cross sections that vanish at high energy,

$$\sigma(ab \longrightarrow cd) \propto \frac{1}{W^{4(1 - \alpha_R(0))}} < \frac{1}{W^2}. \qquad (46)$$

The importance of strong absorption for high-energy hadron interactions is evident from the proximity of central partial waves of *pp* scattering to the unitarity limit, $\Gamma(\mathbf{b}) \le 1$ [101], although the periphery of the nucleon is still gray, and, for all the hadrons, σ_{el} is still substantially smaller than σ_{in} (see the plots in the Review of Particle Physics [102]). As emphasized first by Pomeranchuk, the particle–antiparticle cross-section differences vanish at high energy (see [102]), and from the *t*-channel viewpoint, the elastic scattering is dominated by the vacuum exchange. In 1961, Chew and Frautschi conjectured that the vacuum channel too can be described by the Reggeon—first dubbed the Pomeranchukon, later shortened to Pomeron— exchange with an appropriate spin-2, *C*-even, isoscalar, positive parity resonance lying on the Pomeron trajectory (the early history of the Pomeron is found in [96]).

If the Pomeron were a simple Regge pole, it would have been utterly distinct from the nonvacuum Reggeons.

For all hadrons and real photons, the total cross sections rise with energy and the phenomenological Pomeron trajectory has $\alpha_P(0) = 1 + \Delta_P \approx 1.1 > 1$ (notice that, from now on, the Δ is still used for the four-momentum exchanged, but Δ_{index} is used to define the variation of the intercept of the correspondent *index* trajectory from unity). Such a rise of the vacuum component of the total cross section,

$$\sigma_{\text{vac}} = \sigma_{\text{Pom}} \propto (W^2)^{\Delta_P} \qquad (47)$$

cannot go forever, though. At asymptotic energies, it would conflict the Froissart bound. Furthermore, the partial waves of elastic scattering would overshoot the unitarity bound. Indeed, in the often used exponential approximation, $\frac{1}{W^2}A(W^2, \Delta) \propto \exp\left(-\frac{1}{2}B\Delta^2\right)$, and neglecting the small real part of the small-angle scattering amplitude, one finds

$$\Gamma(\mathbf{b}) = \frac{\sigma_{\text{tot}}}{4\pi B}\exp\left(-\frac{\mathbf{b}^2}{2B}\right), \qquad (48)$$

and with the unlimited growth of σ_{tot}, one would run into $\Gamma(\mathbf{b}) > 1$. The unitarity (absorption, multi-Pomeron exchange, etc.) corrections, which must eventually tame such a growth of $\Gamma(\mathbf{b})$ and of σ_{tot} with energy, were shown to be already substantial at moderate energies [103–105]. The multi-Pomeron absorption substantially affects the determination of Δ_P: the first estimate

$$\Delta_P \sim 0.13$$

with the perturbative treatment of absorption based on Gribov's Reggeon field theory [106, 107] goes back to the 1974–1975 papers by Capella, Tran Thahn Van, and Kaplan [103, 104]. Within a more realistic model for absorption, the ITEP Group [105] found an equally good description of the hadronic cross-section data with substantially larger $\Delta_P \approx 0.23$. If one follows the Donnachie–Landshoff suggestion [108] to ignore the absorption corrections altogether and stick to the simplified pole terms, then the Particle Data Group finds $\Delta_P = 0.095$ [109]. However, according to the 2002 edition of the Review of Particle Properties [102], a better fit to the experimental data is provided by the parametrization [110]

$$\sigma_{\text{vac}}(ab) = \sigma_{\text{vac}}(\bar{a}b) = Z_{ab} + 2B\log^2(W/W_0), \quad (49)$$

which is consistent with the Froissart bound and, from the Regge theory viewpoint, corresponds to the triple-pole singularity at $j = 1$, i.e., $\Delta_P \equiv 0$!

The shrinkage of the diffraction cone in elastic scattering suggests a very small slope of the Pomeron trajectory $\alpha_P(t)$: the combined analysis of the experimen-

tal data on elastic pp, $\bar{p}p$, $\pi^{\pm}p$, $K^{\pm}p$ scattering at the CERN SPS/FNAL and CERN ISR energies gave $\alpha'_P \approx 0.13 \pm 0.025$ GeV^{-2} [111] (for the review, see [112]). The extrapolation of these fits under predicts the $\bar{p}p$ diffraction slope at the Tevatron, which call for $\alpha'_P \approx 0.25$ GeV^{-2}. Incidentally, the last value of α'_P has been used by theorists ever since 1974–1975 [103, 104], but it must be taken with a grain of salt: the observed growth of the diffraction cone can to a large extent be due to the unitarity/absorption driven correlation (cf. Eqs. (44) and (45)) between the total cross section and the diffraction slope, so that the Tevatron data can be reproduced well with the still smaller values of α'_P [113].

To summarize, the Donnachie–Landshoff (DL) parametrization [108]

$$\alpha_{\text{soft}}(t) = 1.1 + 0.25 \text{ GeV}^{-2}t \qquad (50)$$

must only be regarded as a convenient short-hand description of the local, $W < 1$ TeV, energy dependence of the vacuum component of the elastic scattering of hadrons.

3.1.5. The diffraction slope: variations from elastic scattering to single to double diffraction excitation. The variation of the diffraction slope (35) from elastic scattering to single (SD) to double (DD) diffraction excitation exhibits certain universal features [93, 94, 114]. Excellent guidance is provided by a comparison of elastic proton–nucleus, $pA \longrightarrow pA$, to quasi-elastic, $pA \longrightarrow p'A^*$, scattering. The latter reaction that one sums over all excitations and breakup of the target nucleus without production of secondary particle, must be regarded as diffraction excitation of the target nucleus.

The crucial point is that, at a sufficiently large (p, p') momentum transfer such that the recoil energy exceeds the typical nuclear binding energy, which can be viewed as hard scattering, the t-distribution of scattered protons in quasi-elastic (nucleus-dissociative) $pA \longrightarrow p'A^*$ is the same as in elastic pp scattering, $B_{\text{diss}}(pA \longrightarrow p'A^*) \approx B_{pp}$ [115, 116]. The quasi-elastic $pA \longrightarrow p'A^*$ becomes sort of a deep inelastic scattering with quasi-free bound nucleons, behaving as partons of a nucleus and quasi-free $pN \longrightarrow p'N$ scattering, being a counterpart of the Rutherford scattering of leptons off charged partons in DIS off the proton. The summation over breakup of a nucleus into all continuum excitations is important; for excitation of the specific discrete state A^* of a target nucleus, $pA \longrightarrow p'A^*$, the diffraction slope will still be large,

$$B_{AA^*} \sim B_{\text{el}} \approx \frac{1}{4}R_A^2. \qquad (51)$$

Now, define the ratio of differential cross sections

$$\text{Ratio}(\text{diss/el})(t)$$
$$= \frac{d\sigma_{\text{diss}}(pA \longrightarrow p'A^*)}{dt} \bigg/ \frac{d\sigma_{\text{el}}(pA \longrightarrow p'A)}{dt}. \qquad (52)$$

Elastic scattering Ratio$(\text{diss/el})(t) \ll 1$ is the dominant process within the diffraction cone, $R_A^2|t| \ll 1$. However, elastic scattering dies out rapidly for $R_A^2|t| \gtrsim 1$, where quasi-elastic scattering takes over: Ratio$(\text{diss/el})(t) \gg 1$. This point is clearly illustrated by the experimental data [117, 118] on elastic and nucleus-dissociative $p^{12}C$ scattering shown in Fig. 8. Notice the diffractive dip-bump structure, familiar from optical diffraction, in the differential cross section of pure elastic scattering. For a sufficiently hard scattering, $|t| = \Delta^2 \gtrsim 0.06$ GeV^2, the sum of the elastic and nucleus-dissociative cross sections, $d\sigma_{\text{sc}} = d\sigma_{\text{el}} + d\sigma_{\text{diss}}$ is clearly dominated by the nucleus-dissociative $d\sigma_{\text{diss}}$.

In the regime of strong absorption, the integrated cross section of quasi-elastic or nucleus dissociative scattering is small [115],

$$\sigma_{\text{diss}}(pA \longrightarrow p'A^*) \ll \sigma_{\text{el}}(pA \longrightarrow p'A) \approx \frac{1}{2}\sigma_{\text{tot}}^{pA}. \qquad (53)$$

Exactly, the same considerations apply to elastic scattering and diffraction excitation of hadrons and real photons, $a = p, \pi, K, \gamma$ on the free nucleon target, $b = p$. Let B_N be the contribution to the diffraction slope of electric pp scattering from the Pomeron–proton–proton vertex, so that

$$B_{\text{el}}^{pp} = 2B_N + B_P. \qquad (54)$$

In the single or target dissociative (SD) reaction, $pp \longrightarrow pY$, and double dissociation (DD), $pp \longrightarrow XY$, one must distinguish the low-mass (LM; resonances, low-mass continuum states, etc.) and high-mass (HM) states X, Y. The boundary between the low-mass (exclusive low-mass states, resonances, etc.) and high-mass continuum excitations is $M_{X,Y} \sim 2$ GeV. The case of small-mass excitation is an exact counterpart of excitation of discrete nuclear states in $pA \longrightarrow p'A^*$. Then, (51) suggests that the contribution to the diffraction slope from the pY transition $B_{pY} \approx B_N$, so that, in SD and DD, into low-mass states

$$B_{\text{SD}}(\text{LM}) = B_{pY} + B_N + B_P \approx B_{\text{DD}}(\text{LM, LM})$$
$$= B_{pY} + B_{pX} + B_P \approx B_{\text{el}}, \qquad (55)$$

agreeing well with the experimental data from the CERN ISR and FNAL experiments [119–123]. The SD into high-mass (HM) continuum, $pp \longrightarrow pY(\text{HM})$, corresponds to the complete breakup of the target proton, and the reaction can be viewed as elastic scattering of the beam proton on one of the constituents of the target. Consequently, the dependence on the size of the target proton vanishes, $B_{pY} \approx 0$, and in SD into high-mass
Fig. 8. A comparison of elastic (points, the lower set of data points, and the lower curve) and combined elastic plus nucleus-dissociative (triangles, the upper set of data points, and the upper curve) $p^{12}C$ scattering data [117, 118]. The theoretical calculations are from Czyz *et al.* [116].

states (often referred to as the triple-Pomeron region) and mixed low- and high-mass DD

$$B_{SD}(HM) \approx B_D D(LM, HM)$$

$$\approx B_N + B_P \approx \frac{1}{2} B_{el} \approx 6 \text{ GeV}^{-2}. \tag{56}$$

In DD $pp \longrightarrow X(HM)Y(HM)$ with excitation of high-mass states from both the target and beam $B_{pX} \approx B_{pY} \approx 0$ and only the t-channel exchange B_P contributes to diffraction slope. Experimentally, this component is abnormally small [122, 123]:

$$B_{DD}(HM, HM) \approx B_P \sim (1–2) \text{ GeV}^{-2}. \tag{57}$$

Finally, although in πp, Kp, pp scattering, only the central partial waves are close to the strong absorption limit, and the ratios $\sigma_{el}/\sigma_{tot} \sim 0.15$–$0.25$ are still substantially smaller than $1/2$ for the strongly absorbing nuclear target, the strong inequality $\sigma_{dis}(pp \longrightarrow p'Y) \ll \sigma_{el}(pp \longrightarrow pp)$ holds in close similarity to (53). Typically, in pp interactions, $R_{pp}(\text{diss/el}) = \sigma_{SD}/\sigma_{el} \lesssim 0.3$ (for the review, see [93, 94, 112]).

3.2. The Regge Theory and QCD

In the realm of DIS, the high-energy limit amounts to the small-x limit. The SFs of small-x DIS are related to the total cross sections as

$$F_{T,L}(x, Q^2) = \frac{Q^2}{4\pi^2 \alpha_{em}} \sigma_{T,L}(x, Q^2).$$

Instead of the transverse SF, one usually discusses $F_2(x, Q^2) = F_T(x, Q^2) + F_L(x, Q^2)$. The QCD parton model decomposition of the proton SF into the valence and sea quark contributions

$$F_2(x, Q^2) = x \sum_f e_f^2 [q_f(x, Q^2) + \bar{q}_f(x, Q^2)] \tag{58}$$

$$= \frac{4}{9} x u_v(x, Q^2) + \frac{1}{9} x d_v(x, Q^2) + 2x \sum_f e_f^2 \bar{q}_f(x, Q^2)$$

must be viewed as a decomposition of the photoabsorption cross section into the nonvacuum (nonsinglet) and vacuum (singlet) components. From the viewpoint of the QCD evolution, the valence component corresponds to the slowing down of the valence quarks to $x \ll 1$ and depends on the target. At small x, the sea evolves from glue and will be the same for the proton and neutron as well as antinucleon targets; i.e., it must be associated with the Pomeron exchange. The density of small-x gluons greatly exceeds the density of charged partons, which entails that (i) one can model high-energy inelastic interactions by production of the multigluon final states and (ii) to the so-called leading-$\log \frac{1}{x}$, the small-x evolution is driven by the splitting of gluons into gluons, with the splitting $g \longrightarrow q\bar{q}$ only at the last stage of the evolution. As a result, the QCD vacuum exchange is modeled by the tower of color-singlet two-gluon exchange diagrams of Fig. 9, which is described in terms of the so-called unintegrated or differential gluon density

$$\mathcal{F}(x, \kappa^2) = \frac{\partial G(x, \kappa^2)}{\partial \log \kappa^2},$$

where κ is the gluon transverse momentum.

At not so small x, the Q^2-dependence of the parton densities is governed by the DGLAP evolution [124–126]. Here, the evolution goes from smaller to larger Q^2; so that, once the boundary condition is taken at a sufficiently large Q_0^2, then one stays in the perturbative domain. However, in the language of inelastic multiparticle states, the DGLAP evolution amounts to summing only the final states with the strong ordering of transverse momentum, and as such, it accounts to only a small part of the available transverse phase space. This restriction on the transverse phase space becomes excessively prohibitive and must be lifted at very small x.
Fig. 9. (a, b) The subset of two-gluon tower pQCD diagrams for the Pomeron exchange contribution (c) to the Compton scattering (DIS) and diffractive vector meson production. Not shown are two more diagrams with $q \longleftrightarrow \bar{q}$.

The practical method of summing the leading-log $\frac{1}{x}$ contributions to the unintegrated gluon density $\mathcal{F}(x, \boldsymbol{\kappa}^2)$, without restrictions on the transverse momenta of partons, has been developed in 1975 by Fadin, Kuraev, and Lipatov [35, 36] and refined further by Balitsky and Lipatov [37, 127] (for the review, see [128]). One has to pay a heavy price, though the BFKL evolution receives a substantial contribution from soft, nonperturbative transverse momenta of final-state partons, where the running strong coupling α_S is not small and the sensitivity to models of infrared regularization cannot be eliminated ([129–133] and references therein). Although the fully satisfactory quantitative solution to this problem is as yet lacking, many of the properties of the QCD vacuum exchange must be regarded as well established.

Discard the asymptotic freedom; i.e., make the approximation $\alpha_S = \text{const}$, and allow the infinite propagation range for gluons. Such a model is free of a dimensional parameter and possesses the scale-invariance property, which allows for an exact solution. The j-plane singularity of the model is a fixed cut (branching point) [35–37] at

$$-\infty < j \le 1 + \Delta_{\text{BFKL}} = 1 + \frac{12 \log 2}{\pi} \alpha_S \qquad (59)$$

with vanishing $\alpha'_{\text{BFKL}} = 0$, which is natural in view of the lack of any dimensional parameter in the model.

One can cope with the asymptotic freedom within the BFKL approach only at the expense of a certain regularization of the infrared growth of α_S. One only needs to account for the finite propagation length, R_c, of perturbative gluons as suggested, by the lattice QCD studies [50–52]. In their 1975 paper, Fadin, Kuraev, and Lipatov remarked that, in this case, the branching point is superseded by a sequence of moving Regge poles [35]. The positions of the poles were estimated in 1986 by Lipatov [127]:

$$\Delta_n \approx \frac{\Delta_{\text{BFKL}}}{n + 1}. \qquad (60)$$

Herebelow, when discussing the pure Pomeron amplitudes, we will refer to Δ_n as the intercept, which must not cause confusion. Within the color dipole approach, the poles differ by the number of nodes in the eigen cross section as a function of the dipole size r [134]. The rightmost pole has a node-free eigen cross section, the nodal structure of the eigen cross sections and the n-dependence of the intercept of subleading vacuum poles found in [134] are very close to the quasi-classical approximation results of Lipatov [127]. The intercept of the rightmost pole Δ_P, the slopes of the emerging Regge trajectories, and positions of nodes in the eigen cross sections depend on the infrared regularization ([25, 130, 131] and references therein).

3.3. Poor Man's Approximations to the QCD Pomeron

3.3.1. The Q^2-independence of the pomeron intercept. For each and every pole, the intercept does not depend on the probe. In application to DIS that means an independence of intercepts on Q^2 [129–131, 135], only the residues can depend on Q^2, so that the x-dependence of structure functions will be of the form

$$F_2(x, Q^2) = \sum_{n=0} F^{(n)}(Q^2) \left(\frac{1}{x}\right)^{\Delta_n} + F_2^{\text{soft}}(Q^2). \qquad (61)$$

Examples of such a BFKL–Regge expansion for the proton and photon SFs with energy-independent soft contribution $F_2^{\text{soft}}(Q^2)$, i.e., $\Delta_{\text{soft}} = 0$, are found in [134, 136–138]. If one reinterprets the soft contribution in terms of the soft, nonperturbative, unintegrated gluon density, then similar Regge–BFKL expansions hold for the integrated gluon density, $G(x, Q^2)$, and the unintegrated gluon density

$$\mathcal{F}(x, \boldsymbol{\kappa}^2) = \frac{\partial G(x, \boldsymbol{\kappa}^2)}{\partial \log \boldsymbol{\kappa}^2}.$$

An example of the decomposition of $\mathcal{F}(x, \boldsymbol{\kappa}^2)$ into the soft and hard components is found in [34, 139] and is shown in Fig. 10.
Fig. 10. The differential gluons structure function of the proton determined in [34, 139] from the $k_\perp$-factorization analysis of the experimental data on $F_{2p}(x, Q^2)$. Notice the transition from the x-independent soft component at small $\kappa^2 < 1$ GeV^2 (shown by the dashed curve) to the hard component (the dotted curve), which converges to the derivative $\partial G_{\text{DGLAP}}(x, \kappa^2)/\partial\log\kappa^2$ of the integrated gluon density determined from the LO DGLAP fit to $F_{2p}(x, Q^2)$. This particular example is for the GRV LO parametrization [140], very similar results are found for the MRS [141] and CTEQ [142] parametrizations.

From the viewpoint of the energy dependence, the Regge cut can also be viewed as an infinite sequence of Regge poles. One can approximate the local x-dependence of the BFKL–Regge expansion (61) by

$$F_2(x, Q^2) = F(Q^2)\left(\frac{1}{x}\right)^{\Delta(Q^2)}, \qquad (62)$$

which must not be interpreted that the Pomeron is a Regge pole with Q^2-dependent intercept (for such a warning see, for instance, Bjorken [91]). An example of how the effective intercept $\Delta(Q^2)$ changes with the range of x is found in [135, 143, 144], the variations of the effective intercept from the unintegrated gluon density $\mathscr{F}(x, \kappa^2) \propto \left(\frac{1}{x}\right)^{\tau(\kappa^2)}$ to the integrated gluon density $G(x, Q^2) \propto \left(\frac{1}{x}\right)^{\lambda(Q^2)}$ and to the proton SF $F_2(x, Q^2)$ is found in [34, 139] (see Fig. 11), where we show separately the intercept for the hard components of $\mathscr{F}(x, \kappa^2)$, $G(x, Q^2)$, $F_2(x, Q^2)$ and for the same quantities with the soft contributions included. These intercepts parametrize the local x-dependence for $10^{-3} < x < 10^{-5}$. The striking finding is that, while $\tau_{\text{hard}}(\kappa^2)$ and $\lambda_{\text{hard}}(Q^2)$ exhibit a very strong scale dependence; i.e., the contri-

butions from the subleading BFKL poles are large, the $\Delta_{\text{hard}}(Q^2)$ is about Q^2-independent one, $\Delta_{\text{hard}}(Q^2) \sim$ 0.35–0.45.

3.3.2. The contributions from the soft region beyond pQCD. Here, one faces three major questions: (i) Is the rise of soft hadronic cross sections driven by small dipoles in hadrons, (ii) What is the mechanism of interaction of nonperturbative large dipoles, and (iii) Is the soft contribution relevant to the large-Q^2 DIS?

The first question can be answered in the affirmative: the somewhat model-dependent estimates suggest strongly that the rise of the hadronic and real photoabsorption cross sections receive a large if not a predominant contribution from the interaction of small-size color dipoles in hadrons [34, 136]. This suggests a weak energy dependence of the genuine soft vacuum exchange: $\Delta_{\text{soft}} \approx 0$. The discussion of the potential importance of hard contributions to hadronic cross-section was initiated in [113] (for the recent work along these lines, see [145]).

From the color dipole viewpoint, the pure pQCD considerations stop at the dipole size $r \gtrsim R_c \sim 0.2$–0.3 fm and cannot describe the bulk of the hadronic cross-sections. It is plausible that, at such large dipole sizes, the color dipoles spanned between the constituent quarks do still remain the important degrees of freedom, but the corre-
Fig. 11. The effective intercepts $\tau(\kappa^2)$, $\lambda(Q^2)$, $\Delta(Q^2)$ of the local x-dependence, $10^{-3} < x < 10^{-5}$, of $\mathcal{F}(x, \kappa^2)$, $G(x, Q^2)$, $F_2(x, Q^2)$, respectively, for the $k_\perp$-factorization analysis [34, 139] with the large-κ^2 behavior of $\mathcal{F}(x, \kappa^2)$ tuned to the GRV LO parametrization [140] as described in the text. In boxes (a)–(c), the dashed curves are for the hard components; the solid curves are found if the soft components are included. The box (d) shows how the intercepts change from $\mathcal{F}(x, \kappa^2)$ to $G(x, Q^2)$ to $F_2(x, Q^2)$. The very close results are found for intercepts of parametrizations tuned to converge at large Q^2 to the MRS LO [141] and CTEQ LO [142].

sponding soft dipole cross-section remains a model-dependent phenomenological quantity, for which we only have constraints from soft hadronic diffractive scattering or from real or moderate-Q^2 photoabsorption [24, 34, 136, 138]. Such a soft dipole cross-section can be modeled either by the nonperturbative two-gluon exchange [24, 34, 135, 136] or within the closely related model of the stochastic QCD vacuum suggested by the Heidelberg Group [146]. Purely phenomenological attempts to guess the shape of this soft cross-section and its continuation into the hard region [147] should not be disregarded as well.

From the practical point of view, the available models for the dipole cross-section suggest a smooth r-dependence of the dipole cross across $r \sim R_c$ up to $r \sim 1$ fm. Because the pQCD BFKL component of the dipole cross-section rises with energy much faster than the energy-independent soft dipole cross-section, at higher energies, the dominance of the pQCD component of the dipole cross-section will extend beyond $r \sim R_c$, for which reason the lower boundary for the pQCD dominance will be lower than given by Eq. (13). One can come to the same conclusions from the smooth κ^2-dependence of the unintegrated gluon density from soft

to hard region and the dominance of the hard component at large $\frac{1}{x}$ which is clearly seen in Fig. 10.

Regarding the question (iii), even at very large Q^2, the virtual photons contain the hadronic size $q\bar{q}$ components and the SFs receive a nonvanishing, even substantial at $x \sim 10^{-2}$, contribution from the interaction of soft dipole. Within the more familiar DGLAP approach, such a contribution is hidden in the input parton densities; the sensitivity of the DGLAP evolution to the input partons is an old news, although eventually the rising perturbative QCD component would take over at very large Q^2 [134–136]. Recently, there were many suggestions to start with the Regge parametrization of photoabsorption at small to moderate $Q^2 < Q_b^2$ and take $F_2^{(\text{Regge})}(x, Q_b^2)$ as a boundary condition at $Q^2 = Q_b^2$ for the DGLAP evolution at large Q_b^2 ([148–150] and references therein).

3.3.3. The two-pomeron approximation. The transition from the unintegrated gluon density, $\mathcal{F}(x, \kappa^2)$, to the conventional, integrated one, $G(x, Q^2)$, involves an integration, $G(x, Q^2) = \int^{Q^2} (d\kappa^2/\kappa^2) \mathcal{F}(x, \kappa^2)$. Similarly,

to the DGLAP approximation, the small-x SF involves an integration, $F_2(x, Q^2) \propto \int^{Q^2} (d\kappa^2/\kappa^2) G(x, \kappa^2)$. Each integration shifts the nodes to the larger value of Q^2 and, furthermore, enhances the relative contribution from the node-free rightmost eigenfunction. The model-dependent estimates within the color dipole model show that the QCD vacuum exchange contribution to DIS is numerically dominated by the rightmost Pomeron pole plus the energy-independent soft exchange contributions,[2] because the subleading Pomeron pole contributions have a node in the practically important region of $Q^2 \sim 10$–40 GeV^2 [130, 135, 136, 138, 144]. This is the reason behind the remarkable flat Q^2 dependence of $\Delta_{\mathrm{hard}}(Q^2)$ shown in Fig. 11. Consequently, within the kinematical range of HERA, the hard contribution to the proton SF can be well approximated by a simple Regge-pole formula with the intercept $\Delta_{\mathrm{hard}} \sim 0.35$–$0.45$ [34, 139]. This finding is a dynamical justification of the two-pole approximation [145, 154, 155]. The specific models [34, 136, 138] give the concrete Q^2-dependence of the residues; on general grounds, there are no reasons for the decoupling of the effective hard Pomeron from soft amplitudes, including the real photoproduction. We emphasize that the two-Pomeron parametrization only holds in the limited range of x and should not be extrapolated far beyond the kinematical range of HERA.

3.4. The Basics of the Theory of Diffractive Vector Meson Production

Here, we comment briefly on properties of diffractive vector meson production starting with the nonrelativistic quark model in conjunction with the vector dominance model. It offers a useful insight into such fundamental issues as the flavor dependence, the relation between the vector meson production and $V^0 \longrightarrow e^+e^-$ decay, and the way the short-distance wave function of vector mesons is probed in vector meson production. Then, we qualify those properties in the color dipole approach.

3.4.1. The flavor dependence, the relation to the decay $V^0 \longrightarrow e^+e^-$ and VDM. On the one hand, the $V^0 \longrightarrow e^+e^-$ decay amplitude can be parametrized in terms of the matrix element of the electromagnetic current

$$\langle 0|J_\mu|V \rangle = -\sqrt{4\pi\alpha_{em}} g_V c_V V_\mu, \qquad (63)$$

where V_μ is the vector meson polarization vector, so that the decay width equals

<hr>

[2] To this end, it is instructive to recall the early doubts in the necessity of the hard Pomeron contribution for description of the observed cross sections [151–153].
$$\Gamma(V^0 \longrightarrow e^+e^-) = \frac{4\pi\alpha_{em}^2 g_V^2 c_V^2}{3m_V^3}. \qquad (64)$$

Here, the charge-isospin factors c_V are $c_\rho = \frac{1}{\sqrt{2}}(e_u - e_d) = \frac{1}{\sqrt{2}}$, $c_\omega = \frac{1}{\sqrt{2}}(e_u + e_d) = \frac{1}{3\sqrt{2}}$, $c_\phi = e_s = -\frac{1}{3}$, $c_{J/\Psi} = e_c = \frac{2}{3}$, $c_\Upsilon = e_b = -\frac{1}{3}$. One also often uses the parameter

$$\frac{1}{f_V} = \frac{g_V c_V}{m_V^2}.$$

On the other hand, in the nonrelativistic quark model, the vector meson is the weakly bound spin-triplet, S-wave $q\bar{q}$ state, and the decay $V^0 \longrightarrow e^+e^-$ proceeds via annihilation $q\bar{q} \longrightarrow e^+e^-$,

$$\Gamma(V^0 \longrightarrow e^+e^-) = |R_V(0)|^2 \langle v_{q\bar{q}}\sigma(q\bar{q} \longrightarrow e^+e^-)\rangle$$
$$= \frac{4\alpha_{em}^2 c_V^2}{m_V^2}|R_V(0)|^2, \qquad (65)$$

where $v_{q\bar{q}}$ is the relative velocity of the quark and antiquark in the vector meson and $R_V(0)$ is the radial wave function at the origin [156]. This gives a useful relationship

$$g_V = R_V(0)\sqrt{\frac{3m_V}{\pi}}, \qquad (66)$$

which amounts to the nonrelativistic calculation of the Feynman diagram of Fig. 12.

Consequently, in the simplified VDM approximation, for transverse photons,

$$\mathcal{T}(\gamma^* p \longrightarrow Vp) = \frac{\sqrt{4\pi\alpha_{em}} g_V c_V}{Q^2 + m_V^2}\mathcal{T}(Vp \longrightarrow Vp) \quad (67)$$

$$= \sqrt{\frac{3\Gamma(V^0 \longrightarrow e^+e^-)}{m_V\alpha_{em}}}\frac{m_V^2}{Q^2 + m_V^2}\mathcal{T}(Vp \longrightarrow Vp) \quad (68)$$

$$= \frac{c_V R_V(0)\sqrt{12\alpha_{em}m_V}}{Q^2 + m_V^2}\mathcal{T}(Vp \longrightarrow Vp). \qquad (69)$$

Precisely the same result is found if one computes the vector meson production amplitude through the diagrams of Fig. 13 and applies the additive quark model,

$$\mathcal{T}(Vp \longrightarrow Vp)$$
$$= \mathcal{T}(qp \longrightarrow qp) + \mathcal{T}(\bar{q}p \longrightarrow \bar{q}p). \qquad (70)$$

In the case of the ρp and ωp final states, a very good parameter free description of the E401-FNAL measurements of the differential cross section of photoproduc-

Fig. 12. The decay of the vector meson into the lepton pair via annihilation $q\bar{q} \longrightarrow e^+ e^-$.

tion is found if one takes isoscalar elastic πN scattering amplitudes for $\mathscr{T}(Vp \longrightarrow Vp)$ ([43, 157] and references therein). The sp, $\bar{s}p$ amplitudes needed for the ϕp state can be extracted from the πN, KN, $\bar{K}N$ elastic scattering amplitudes

$$\mathscr{T}(\phi p \longrightarrow \phi p) = \mathscr{T}(K^+ p \longrightarrow K^+ p)$$
$$+ \mathscr{T}(K^- p \longrightarrow K^- p) - \mathscr{T}(\pi^- p \longrightarrow \pi^- p), \quad (71)$$

which gives a perfect description of the t-dependence of the E401-FNAL data on photoproduction of ϕp [157]. Specifically, (71) correctly reproduces the experimentally observed change of the diffraction slope from $B(\gamma p \longrightarrow \omega p) = 12.6 \pm 2.3$ GeV^{-2} to $B(\gamma p \longrightarrow \phi p) = 6.8 \pm 0.8$ GeV^{-2}. In terms of the discussion in Section 3.1.3 (see Eq. (35)), this inequality of diffraction slopes suggest that the spatial size of the ϕ made of the heavier strange quarks is substantially smaller than the spatial size of the ω made of the light u, d quarks. However, the observed differential cross section is only a half of what is predicted by (68) and (71). Within the color dipole approach, the culprit is the oversimplified VDM approximation (71): the interaction of the quarkonium is controlled by not the number and flavor of quarks in the state but rather its size [158].

3.4.2. Vector meson production in the color dipole approach. In the color dipole approach, thanks to Lorentz dilation of time at high energies, the partonic fluctuation (to the lowest order, $q\bar{q}$ pair) of the incident photon is frozen in transverse (impact parameter) space during the interaction with the target. This allows one to cast the photoproduction amplitude in a quantum-mechanical form [17, 19, 21]

$$\mathscr{T} = \langle \Psi_V | \hat{\sigma}_{\mathrm{dip}} | \Psi_\gamma \rangle = \int dz d^2 \mathbf{r} \Psi_V^*(\mathbf{r}) \sigma_{\mathrm{dip}}(x, \mathbf{r}) \Psi_\gamma(\mathbf{r}), (72)$$

where z and $(1 - z)$ are fractions of the photon's light-cone momentum carried by the quark and antiquark,

respectively. The basic quantity here, the cross section of the color dipole interaction with the target $\sigma_{\mathrm{dip}}(\mathbf{r})$, can be calculated for the forward scattering case through the unintegrated gluon distribution,

$$\sigma_{\mathrm{dip}}(x, \mathbf{r})$$
$$= \frac{4\pi}{3} \int \frac{d^2 \boldsymbol{\kappa}}{\kappa^4} \mathscr{F}(x, \boldsymbol{\kappa}) \alpha_s [\max(\boldsymbol{\kappa}^2, A/\mathbf{r}^2)][1 - \exp(i\boldsymbol{\kappa}\mathbf{r})], \quad (73)$$

where

$$A \sim 9\text{--}10 \quad (74)$$

follows from the properties of Bessel functions [33]. Equations (72) and (73) sum to the leading $\log \frac{1}{x}$ the towers of two gluon exchange diagrams of Fig. 9, as manifested by the unintegrated glue $\mathscr{F}(x, \boldsymbol{\kappa})$ in the integrand of (72). The x-dependence of the dipole cross section is governed by the color dipole BFKL equation [129, 159, 160] (see also [161, 162]); for the discussion of the choice,

$$x = x_g \approx 0.4 \frac{Q^2 + m_V^2}{W^2} \quad (75)$$

(see Section 4.6 below).

In due turn, the unintegrated glue of the proton can be extracted from the experimental data on the proton structure function [34, 139], so that there is a microscopic QCD link between inclusive DIS and vector meson production, if the vector meson is treated in the $q\bar{q}$ Fock-state approximation. For small dipoles, there is a useful relationship to the integrated gluon structure function of the proton [33, 163]

$$\sigma_{\mathrm{dip}}(x, \mathbf{r}) = \frac{\pi^2}{3} r^2 \alpha_S \left(\frac{A}{r^2}\right) G\left(x, \frac{A}{r^2}\right). \quad (76)$$

Now comes the crucial point: the light-cone wave function of the virtual photon shrinks with Q^2, namely, $\Psi_\gamma(\mathbf{r}) \propto \exp(-\epsilon r)$, where [17–19]

$$\epsilon^2 = z(1 - z)Q^2 + m_f^2, \quad (77)$$

where m_f is the mass of the flavor quark f. Then, for a sufficiently large Q^2, the dominant contribution to the virtual photoproduction amplitude will come from $r \sim r_S = 3/\epsilon$, so that

Fig. 13. The additive quark model approximation for the vector meson production amplitude.

$$\mathcal{T} \propto c_V r_S^2 \sigma_{\mathrm{dip}}(x_g, r_S) \Psi_V^*(z, r_S)$$
$$\propto r_S^4 \alpha_S\!\left(\frac{A}{r_S^2}\right) G\!\left(x_g, \frac{A}{r_S^2}\right), \tag{78}$$

where, in the integrand of (78), the z-dependent factors coming from the photon wave function have been suppressed.

Note that the "quark mass" term m_f^2 here must not be omitted even for the light flavors. This "quark mass" serves as an effective parameter that bounds from above the transverse size of the $q\bar{q}$ state in a real photon. One can discuss the large-size properties of the photon only under certain assumptions on the color-dipole cross section for large dipoles or the unintegrated gluon density for nonperturbative soft gluon momenta: the early choice has been $m_{u,d} \approx 0.15$ GeV [134, 135], the more recent $k_\perp$-factorization analysis [34] of the low-Q^2 F_{2p} data suggests $m_{u,d} \approx 0.22$ GeV.

The result (78) has all the properties of the amplitude (69) subject to important QCD modifications:

The color-dipole cross section is flavor-independent, and the charge-isospin factors are precisely the same as in the VDM.

For $r_S \ll R_V$, the vector meson production is obviously short-distance dominated and tractable within pQCD [17–19, 22, 23] (for refinements on the applicability of pQCD, see Collins [164]). The amplitude is proportional to the vector meson wave function at vanishing transverse $q\bar{q}$ separation, $\Psi_V^*(z, 0)$, which is closely related to the so-called vector meson distribution amplitude [165, 166].

To the nonrelativistic approximation, $z \sim 1/2$ and $m_V \approx 2m_q$, one has $\epsilon^2 \approx \frac{1}{4}(Q^2 + m_V^2)$, and the factor $r_S^2 \propto 1/(Q^2 + m_V^2)$ reproduces the Q^2 dependence dictated by the vector meson propagator.

However, $\sigma_{\mathrm{tot}}(Vp \longrightarrow Vp)$, which enters (69), is substituted for by

$$\sigma_{\mathrm{dip}}(x_g, r_S) \approx \frac{3\pi^2}{\overline{Q}^2} \alpha_S(\overline{Q}^2) G(x_g, \overline{Q}^2), \tag{79}$$

where we used (74) and (9) by which $A/r_S^2 \approx \overline{Q}^2$. For large dipoles, $r_S \sim R_V$, which dominate in real photoproduction, $\sigma_{\mathrm{dip}}(R_V) \approx \sigma_{\mathrm{tot}}(Vp \longrightarrow Vp)$, but, for small dipoles, $r_S \ll R_V$, which dominate electroproduction, $\sigma_{\mathrm{dip}}(x_g, r_S) \ll \sigma_{\mathrm{tot}}(Vp \longrightarrow Vp)$, and the simplified VDM is bound to fail.

For small scanning radii, $r_S \ll R_V$, such that $\Psi_V(z, r_S) \approx$ const, the dependence on Q^2 and the mass of the vector meson m_V only enters through the scanning radius r_S. Hence, the fundamental prediction [21] that cross sec-

tions for different vector mesons taken at the same value of r_S, i.e., the same value of $(Q^2 + m_V^2)$, must exhibit similar dependence on energy and $(Q^2 + m_V^2)$.

Vector meson production probes the integrated gluon SF of the target proton at hard scale $\overline{Q}^2$ given by (8) [20–22] (for a more accurate definition of $\overline{Q}^2$ for light vector mesons, see [38]).

Notice an inapplicability of the simplified VDM to heavy quarkonia, for which, by virtue of small α_S, the Bohr radius

$$R_V = a_B \approx \frac{4}{m_V \alpha_S} \gg r_S. $$

Finally, as far as the t-dependence is concerned, r_S can be regarded as the transverse size of the $\gamma^* \longrightarrow V$ transition vertex, so that, for the fixed value of x, the diffraction slope is predicted [25, 26] to decrease with $(Q^2 + m_V^2)$:

$$B(Q^2) \sim B_N + C r_S^2 \approx B_N + \frac{\mathrm{const}}{Q^2 + m_V^2}. \tag{80}$$

Because the color dipole cross section and the unintegrated gluon SF are related by the Fourier transform, all the above results can be rederived in the momentum space representation, often referred to as the $k_\perp$-factorization or impact factor representation. The relevant formalism goes back to the 1978 seminal paper by Balitsky and Lipatov [37], although the term "$k_\perp$-factorization" has been coined much later on by several groups [167–169]. The detailed application of the $k_\perp$-factorization to the vector meson production is found in [54, 170–172] and will be reviewed in the following Section 4; the first momentum space derivation of the leading $\log \overline{Q}^2$ approximation is due to Ryskin [22] and Brodsky *et al.* [23]; some corrections to the leading $\log \overline{Q}^2$ approximation were discussed by Levin *et al.* [173]. Referring to Section 4 for a detailed discussion of the helicity amplitudes within $k_\perp$-factorization, here we only cite the gross features of the longitudinal and transverse cross-sections:

$$\sigma_T \propto \frac{1}{(Q^2 + m_V^2)^4}[\alpha_S(\overline{Q}^2) G(x_g, \overline{Q}^2)]^2, \tag{81}$$

$$\sigma_L \propto \frac{Q^2}{m_V^2} \frac{1}{(Q^2 + m_V^2)^4}[\alpha_S(\overline{Q}^2) G(x_g, \overline{Q}^2)]^2. \tag{82}$$

Here, the factor $\sim Q^2/m_V^2$ in the σ_L is a generic consequence of the electromagnetic gauge invariance, as has been understood in early 1970s [174, 175].

The Heidelberg Group [176] starts with the soft color dipole cross section evaluated within the stochas-

tic QCD vacuum model [146]. It shares with other color dipole models the predictions for the Q^2 dependence, but the energy dependence does not follow from the first principles of the model and needs to be introduced by hand [177].

3.4.3. Production of excited vector mesons. The ρ^0, ω^0, ϕ^0, and J/ψ are the ground-state vector mesons. The $\Psi'(3686)$ is the well-established radial excitation $2S$-state, the $\Psi''(3770)$ is a solid candidate for the orbital excitation D-wave state [47, 48], the radial vs. orbital excitation assignment in the ρ, ω, ϕ family is not yet definitive [102].

The salient feature of the $2S$ radial excitations is a node of the radial wave function, $\Psi_{2S}(z, r)$, at $r = r_{node} \sim R(1S) = R_V$, which suppresses the $V'(2S)$ production amplitude in comparison to the corresponding $V(1S)$ production amplitude [17, 18, 49, 178]. The strength of the node effect depends on the proximity of the scanning radius r_S to the node position r_{node}. At $r_S \ll r_{node}$ (in the undercompensation regime), which can take place at high Q^2 or for very heavy mesons, the contribution from $r > r_{node}$ is small and suppression is weak. The undercompensation regime is relevant to the $\Psi'(2S)$ production, where the color dipole model predicts the rise of the ratio $\sigma(\Psi'(2S))/\sigma(J/\psi(1S))$ with rising Q^2. For light vector mesons, at small Q^2, the overcompensation scenario of $r_S \gtrsim r_{node}$ and strong cancellation is not excluded [26, 49, 178]. In this scenario, the $V'(2S)$ and $V(1S)$ production amplitudes will be of the opposite sign, which can be tested experimentally via the Söding–Pumplin effect [179, 180], and the differential cross sections $d\sigma(V'(2S))/dt$ may exhibit a sharp forward dip [26, 49, 54]. In such a regime, even a small shift of Q^2 would strongly alter the cancellation pattern, giving rise to an anomalous Q^2 dependence of the ratio $\sigma(V'(2S))/\sigma(V(1S))$, of the t-dependence of $d\sigma(V'(2S))/dt$, and of the ratio σ_L/σ_T for the $V'(2S)$; the latter effect is due to a slightly different impact of the node effect on different helicity amplitudes. A subsequent discussion of sensitivity of the node effect to the wave function of vector mesons is found in [181–184]; the change of numerical results for the $\Psi'(2S)$ from one model to another must be regarded as marginal.

The case of the orbital excitation $V''(D)$ is quite different [171]: here, the radial wave function vanishes at the origin, and the Q^2 dependence of the $V''(D)$ production will be smooth. There are some subtle changes in the helicity amplitudes: in both the $V(1S)$ and $V''(D)$, the $q\bar{q}$ pair is in the spin-triplet state, but the total spin of the pair is along in $V(1S)$, and opposite to in $V''(D)$, the spin of the meson.

The node effects echoes in the hard scale for the $V'(2S)$ production. In the undercompensation regime of relevance to the $\Psi'(2S)$, the contribution to the production amplitude from large color dipoles, $r > r_{node}$, is canceled by the contribution from small dipoles, $r < r_{node}$. As a result, the $\Psi'(2S)$ production amplitude is domi-

nated by color dipoles of smaller size than it is the case for the $J/\Psi(1S)$, and color dipoles models predict the hierarchy of hard scales $\overline{Q}^2(\Psi'(2S)) > \overline{Q}^2(J/\Psi(1S))$. Consequently, the $\Psi'(2S)$ production amplitude must grow faster with energy than the $J/\Psi(1S)$ production amplitude [49]. Furthermore, the negative-valued contribution to the production amplitude from large dipoles, $r > r_{node}$, has a steeper t-dependence than the positive-valued contribution from small dipoles, $r > r_{node}$. As a result, the diffraction slope in the $\Psi'(2S)$ production is predicted to be smaller than in the $J/\Psi(1S)$ production [26, 49].

3.4.4. Unitarity and saturation in the color dipole language. The unitarization of rising scattering amplitudes in QCD remains one of the hot, and as yet, unsolved issues. As emphasized in Section 3.1.4, the unlimited growth of the model partial waves must be tamed and the unitarity bound $\Gamma(\mathbf{b}) \leq 1$ must be met in a consistent treatment of high-energy scattering. The theory is still in the formative stage, though. Some of the early works on unitarization have been mentioned in Section 3.1.4; the problem of unitarity is most acute for interactions with nuclei, in which case the impulse approximation partial waves $\Gamma_0(\mathbf{b}) \propto A^{1/3}$. For the nuclear targets, the presence of a new large parameter—the optical thickness of a nucleus—leads to certain simplifications like the applicability of the eikonal approximation for the color dipole-nucleus scattering [24, 185–189]. The recent development in imposing the unitarity on nuclear amplitudes, often referred to as the color glass condensate, is summarized in [190–193] (for a review of the early works, see [194, 195]). A review of the enormous literature on the subject goes beyond the scope of this review; we would rather present a brief introduction into major ideas.

Let $\Gamma_0(\mathbf{r}, \mathbf{b})$ be the profile function for the color dipole-nucleon scattering evaluated in the single-Pomeron exchange approximation of Fig. 9. The Gaussian approximation (48) is not imperative but convenient for the sake of illustration. In the full-fledged QCD, one needs to sum all multigluon t-channel exchanges between the color dipole and nucleon, including interactions between all exchanged not shown in Fig. 14a. A poor man's approximation to this as yet unsolved problem ([196, 197] and references therein) is the multiple exchange by bare Pomerons; in general case, the interactions between gluons from different Pomerons must be included. When the multi-Pomeron exchanges are evaluated in the eikonal approximation, one obtains the "unitarized" profile function [163]

$$\Gamma(\mathbf{r}, \mathbf{b}) = 1 - \exp[-\Gamma_0(\mathbf{r}, \mathbf{b})], \quad (83)$$

whereas the so-called K-matrix unitarization gives [163]

$$\Gamma(\mathbf{r}, \mathbf{b}) = \frac{\Gamma_0(\mathbf{r}, \mathbf{b})}{1 + \Gamma_0(\mathbf{r}, \mathbf{b})}. \quad (84)$$
Fig. 14. (a) The multigluon *t*-channel exchange diagram contribution to the color dipole scattering amplitude and (b) its approximation by multiple exchange by the two-gluon Pomerons.

The latter has been suggested also from the consideration of the so-called fan diagrams [198] (similar results are found from different approximate nonlinear evolution equations [199, 200]; for the so-called *U*-matrix approach, see [201]).

The principal point is that the unitarized partial waves do always respect the unitarity bound $\Gamma_0(\mathbf{r}, \mathbf{b}) \leq 1$. The partial waves saturate at the black-disc limit, $\Gamma(\mathbf{r}, \mathbf{b}) \approx 1$, for all impact parameters such that $\Gamma_0(\mathbf{r}, \mathbf{b}) \gg 1$, i.e.,

$$\mathbf{b}^2 \lesssim 2B(\mathbf{r})\log\Gamma_0(\mathbf{r}, \mathbf{b} = 0). \tag{85}$$

The two unitarized forms (83) and (84) only differ by the rate of approach to the black disc limit, the *K*-matrix unitarized dipole cross section takes a particular simple form [163]:

$$\sigma(x, \mathbf{r}) = 4\pi B(\mathbf{r})\log\left(1 + \frac{\sigma_0(x, \mathbf{r})}{4B(\mathbf{r})}\right), \tag{86}$$

which shows clearly how the powerlike small-*x* growth of the bare Pomeron cross section $\sigma_0(x, \mathbf{r}) \propto x^{-\Delta_P}$ is superseded by the $\propto \log\frac{1}{x}$ behavior, or $\propto \log^2\frac{1}{x}$ if one allows the Regge growth of the diffraction slope $B(x, \mathbf{r})$ [202].

Finally, the unitarization alters dramatically the **r**-dependence of the dipole cross section from (76). At asymptotically small *x*, the unitarization is at work already for small dipoles, where the **r**-dependence of diffraction slope $B(x, \mathbf{r})$ can be neglected (see (80)), so that the dipole cross section would saturate, $\sigma(x, \mathbf{r}) \approx 4\pi B$; for dipoles,

$$\mathbf{r}^2 \gtrsim r_{\text{sat}}^2 = \frac{12B}{\pi\alpha_S(r)G(x, q^2 = A/r^2)}. \tag{87}$$

The smaller *x* is, the larger is the gluon SF in the numerator in the right-hand side of (87) and the smaller is the saturation scale r_{sat}^2. Recently, specific parametrizations for the saturating dipole cross section without an explicit reference to the unitarity properties of partial waves have been proposed [147, 203]. (In principle, the saturation rate and the saturated cross section must be adjusted to describe the diffractive hadronic scattering and real photoproduction [3, 24], which has not been done in the model [147, 203].) However, with the realistic dipole cross sections, the unitarization effects for

DIS [163] and for vector meson production [21] were found to be marginal. The extraction of the *S*-matrix for the color dipole scattering from the vector meson production data by Munier, Mueller, and Stasto also shows that the dipole-nucleon scattering is not yet close to the strong absorption regime [204]. Similar conclusion follows from the impact parameter extension [205] of the saturation model [147, 203]. Those findings are not surprising, though, as shown in [4], in the limit of strong saturation, the diffractive rapidity gap DIS must make precisely 50% of the total DIS cross section, whereas, experimentally, the fraction of diffractive DIS is about 10% [1, 2].

To summarize, as soon as the impact parameter dipole model has been adjusted to fit the experimental data on DIS structure functions and the total cross section and the *t*-dependence of diffractive vector meson production, it is expected to have partial waves consistent with the unitarity constraints in the energy and Q^2 range in which the experimental data are available. The same must be true of the unintegrated gluon SF of the proton extracted in [34] from the DIS data. Applying unitarity corrections to the vector meson production amplitudes evaluated with such an unintegrated gluon SF would be double counting.

3.4.5. Color dipole model and generalized VDM. The simplified VDM must be regarded as the leading term of the mass-dispersion relation calculation of the Q^2 dependence of the virtual photoproduction amplitude. The importance of contributions from the more distant singularities—the higher vector states and the continuum, which we denote generically as V_i—rises with Q^2 [174, 175, 206]. Within the resulting generalized VDM (GVDM) for DIS, the calculation of $\gamma^*p \longrightarrow \gamma^*p$ must allow for transitions of photons to all higher vector states, $\gamma^* \longrightarrow V_i$, followed by the diagonal and off-diagonal scattering $V_ip \longrightarrow V_jp$ and the transition $V_j \longrightarrow \gamma^*$ (see Fig. 15).

Similarly, the transitions $\gamma^* \longrightarrow V_i$ followed by the off-diagonal scattering $V_ip \longrightarrow Vp$ would contribute to the vector meson production $\gamma^*p \longrightarrow Vp$. If, viewed as the mass dispersion relation, the GVDM cannot fail, but the practical application requires the knowledge of all the diagonal and off-diagonal amplitudes $V_ip \longrightarrow V_jp$ and of the Q^2 dependence of transitions $\gamma^* \longrightarrow V_i$. The color dipole model provides the QCD input for the GVDM analysis [18, 207], the equivalence of the two
Fig. 15. The generalized vector dominance model diagrams for Compton scattering (DIS) and diffractive vector meson production.

approaches emphasized in [24] has been elaborated in [208].

3.4.6. The s-channel helicity nonconservation (SCHNC). The scattering of the $q\bar{q}$ dipole on the target via exchange of the two-gluon tower exactly conserves the *s*-channel helicity of the quark and antiquark (for the QED case, see [209, 210]). This does not imply the conservation of the helicity of photons in the off-forward Compton scattering. As a spin-1 particle, photon is similar to the deuteron. In the nonrelativistic case, the pure *S*-wave deuteron with spin up consists of the spin-up proton and spin-up neutron; the longitudinal deuteron consists of the spin-up proton and spin-down neutron, and vice versa.

The perturbative QED transition of the photon to the $q\bar{q}$ pair is described by the familiar vertex $e_f\bar{q}\gamma_\mu q A_\mu$. The longitudinal (scalar) virtual photon with helicity $\lambda_\gamma = 0$ consists of the $q\bar{q}$ Fock state with $\lambda + \bar{\lambda} = \lambda_\gamma = 0$, in close similarity to the *S*-wave deuteron. The crucial point is that the transverse photon with helicity $\lambda_\gamma = \pm 1$ besides the $q\bar{q}$ state with $\lambda + \bar{\lambda} = \lambda_\gamma = \pm 1$ contains the state with $\lambda + \bar{\lambda} = 0 \neq \lambda_\gamma$, in which the helicity of the photon is carried by the orbital angular momentum in the $q\bar{q}$ system (see [211] for an early discussion of this mechanism in application to the spin-flip in the nucleon scattering). Furthermore, it is precisely the chiral-even state with antiparallel helicities, $\lambda + \bar{\lambda} = 0$, which gives the dominant contribution to the absorption of transverse photons and the proton SF $F_{2p}(x, Q^2)$ in the Bjorken limit. The perturbative transition of transverse photons to the chiral-odd state with parallel helicities, $\lambda + \bar{\lambda} = \lambda_\gamma = \pm 1$, vanishes in the massless quark limit.

The helicity structure of vector mesons is about the same. From the point of view of the vector meson production, it is important that the transverse and longitudinal γ^* and V share the intermediate $q\bar{q}$ state with $\lambda + \bar{\lambda} = 0$, which allows the *s*-channel helicity nonconserving (SCHNC) transitions between the transverse (longitudinal) γ^* and longitudinal (transverse) vector meson V [170, 212]. This mechanism of SCHNC does not require an applicability of pQCD.

Hereafter, we only discuss the experimental data from HERA taken with unpolarized protons; hence, the proton can be treated as a spinless particle (see, however, a brief discussion in Section 5.5). Depending on

the spin–parity of the *t*-channel exchange, the helicity amplitudes satisfy [213]

$$\mathcal{T}_{-\lambda_V -\lambda_\gamma} = \pm(-1)^{\lambda_V - \lambda_\gamma}\mathcal{T}_{\lambda_V \lambda_\gamma}, \tag{88}$$

where the + (–) sign applies to natural (unnatural) parity exchange. As discussed in Section 3.1.2, Pomeron and all the highest lying subleading Reggeons have the natural spin–parity. Under the dominance of the natural spin–parity exchange, the number of independent helicity amplitudes is reduced to five:

$$\begin{aligned} L &\longrightarrow L, \quad T \longrightarrow T \quad (\lambda_\gamma = \lambda_V) \\ T &\longrightarrow L, \quad L \longrightarrow T; \\ T &\longrightarrow T' \quad (\lambda_\gamma = -\lambda_V). \end{aligned} \tag{89}$$

The first line contains helicity-conserving amplitudes. They are predicted and found to be the dominant ones. They do not vanish for the forward production, $\mathbf{\Delta} = 0$. The second line in (89) contains two single helicity-flip amplitudes. They must be proportional to $|\mathbf{\Delta}|$ in the combination $(\mathbf{e} \cdot \mathbf{\Delta})$ or $(\mathbf{V}^* \cdot \mathbf{\Delta})$, since there is no other transverse vector at our disposal. The last line contains the double helicity-flip amplitude, which must be proportional to $(\mathbf{e} \cdot \mathbf{\Delta})(\mathbf{V}^* \cdot \mathbf{\Delta})$.

One can thus predict that the *s*-channel helicity conserving amplitudes will dominate in the almost forward production of mesons. As *t* increases, the relative importance of helicity-flip amplitudes will grow, and at high enough *t* they might become competitive to the helicity-conserving amplitudes.

3.4.7. Diffractive vector meson production from extended bloom–gilman duality. The Bloom–Gilman inclusive–exclusive duality relates the $x \longrightarrow 1$ behavior of DIS to elastic *ep* scattering [214]. Roughly speaking, if one stretches the *x*-dependence of the DIS cross section determined for the continuum masses W to the elastic limit $W \longrightarrow m_p$, then the DIS cross section integrated over the interval

$$0 < 1 - x < \frac{W_0^2 - m_p^2}{Q^2} \tag{90}$$

will, with the judicious choice of the duality interval $[m - p, W_0]$, be equal to the elastic *ep* cross section (for the recent active discussion of duality in DIS in connection with the JLab data, see [215]). Genovese *et al.* argued [216] that similar parton-duality relationship must hold between the diffraction excitation of the small-mass continuum

$$ep \longrightarrow e'Xp'$$

and exclusive vector meson production. In terms of the diffractive Bjorken variable

$$\beta = \frac{Q^2}{Q^2 + M_X^2}$$

the diffractive structure functions for the transverse and longitudinal photons have the large-β behavior [216–218]:

$$F_T(x, \beta, Q^2) \propto (1 - \beta)^2 G^2(x, q_T^2), \qquad (91)$$

$$F_T(x, \beta, Q^2) \propto \frac{1}{Q^2} G^2(x, q_L^2). \qquad (92)$$

The relevant hard scales equal [216, 217, 219]

$$q_T^2 \sim \frac{m_q^2}{M_X^2}(Q^2 + M_X^2), \quad q_L^2 \sim \frac{1}{4}(Q^2 + M_X^2). \qquad (93)$$

The integration over the duality interval $[M_{\min} \sim 2m_q, M_{T,L}]$, i.e., $1 - \beta_{T,L} < M_{T,L}^2/Q^2$, yields the correct large-Q^2 dependence of $\sigma_{L,T}$. Furthermore, both hard scales $q_{T,L}^2$ tend to the scale $\overline{Q}^2$ of Eq. (8), so that Eqs. (91) and (92) yield precisely the same dependence on the gluon structure function as in (80) and (81). Motivated by this observation [216], Martin *et al.* suggested to evaluate the vector meson production cross sections $\sigma_{T,L}$ from the duality integral [220, 221]. This way, one encounters a very strong sensitivity of such evaluations of $\sigma_{T,L}$ to the duality interval

$$\sigma_T \propto (M_T^6 - M_{\min}^6), \qquad (94)$$

$$\sigma_L \propto (M_L^2 - M_{\min}^2), \qquad (95)$$

which is especially strong in the case of σ_T.

Similar in spirit to the duality is the unorthodox color evaporation model (CEM). In its original formulation [222], it simply states that the color of the $q\bar{q}$ pair produced in $\gamma^*g \longrightarrow q\bar{q}$ subprocess happens to be bleached by soft final-state interactions leading to the rapidity gap events, with the probability 1/9. Within CEM, the charmonium production is described by the formation of colored open charm $c\bar{c}$ states which masses $M_{c\bar{c}} \leq 2m_D$, where m_D is the mass of the D-meson [223]:

$$\sigma_{\text{onium}} = \frac{1}{9} \int\limits_{2m_c}^{2m_D} dM_{c\bar{c}} \frac{d\sigma_{c\bar{c}}}{dM_{c\bar{c}}}, \qquad (96)$$

where 1/9 is the color bleaching probability. Assuming that about 50% of the onium goes into the J/Ψ, Amundson *et al.* are able to describe the photo- and hadro-production of the J/Ψ [224, 225]. Gay Ducati *et al.* find a similar agreement with the total cross section of elastic

charmonium photoproduction [226, 227]. Here, we only notice that in the near-threshold process $\gamma^*g \longrightarrow c\bar{c}$ produces the spin-singlet S-wave $c\bar{c}$ pair. Arguably, the color bleaching cannot flip the spin of nonrelativistic heavy quarks, and that must lead to strong suppression factor in the estimate (96). In contrast to that, in hadronic collisions, the near-threshold open charm can be produced in the spin-triplet state via $q\bar{q}$, $gg \longrightarrow g \longrightarrow c\bar{c}$, and the spin dynamics of heavy nonrelativistic quarks does not prohibit the formation of J/Ψ by color bleaching.

3.4.8. Models which respect the froissart bound. Only a limited range of energy, x, and Q^2 is spanned by the available experimental data. We already mentioned an equally good description of the available soft cross section data by the soft Pomeron pole exchange and logarithmic parametrizations (see Section 3.1.4). We also recall an observation by Buchmüller and Haidt [228] that gross features of the small-x proton structure function as measured at HERA are reasonably well reproduced by a very simple parametrization

$$F_2(x, Q^2) = a + m\log\frac{x_0}{x}\log\frac{Q^2}{Q_0^2}. \qquad (97)$$

From the Regge theory viewpoint, this corresponds to the dipole singularity at $j = 1$. The dipole singularity model for virtual photoproduction of vector mesons has been proposed by Fiore *et al.* [229, 230]; in this specific example, the nonlinear Pomeron trajectory with the branching point singularity at the two-pion threshold in the t-channel is used. For each and every vector meson, a good description of the vector meson production cross sections is found at the expense of five free parameters. A very closely related model was proposed by Martynov *et al.* [231, 232]. Troshin and Tyurin suggested a parametrization of vector meson production amplitudes in which the high-energy growth is tamed by the U-matrix unitarity constraints [201]. Haackman *et al.* [233] start with the soft Pomeron with $\Delta_P > 0$ and impose the unitarization by Reggeon field theory methods as mentioned in Section 3.1.4. The drawback of such models is that the Q^2 dependence of the vector meson production is parametrized rather than predicted from the microscopic QCD.

4. THE $k_\perp$-FACTORIZATION: UNIFIED MICROSCOPIC QCD DESCRIPTION OF DIS AND VECTOR MESON PRODUCTION

4.1. The Leading $\log\frac{1}{x}$ *and* $q\bar{q}$ *Fock State*

Approximations

The color dipole and k_t-factorization approaches to small-x DIS are conjugate to each other; the technical correspondence is given by Eq. (73). The advantage of the former is its simple quantum-mechanical represen-

tation, still some technical issues such as the definition of the light-cone wave functions, the separation of the *S*-wave and *D*-wave states of vector mesons, and the role of the so-called skewed, or off-diagonal, gluon distribution functions are more transparent in the momentum-space representation.

The starting point is the BFKL diagram for small-*x* DIS (Fig. 9), and the reference reaction is the nonforward Compton scattering $\gamma^* p \longrightarrow \gamma^*(\Delta)p(-\Delta)$. The vector meson production is obtained from the Compton diagram replacing the outgoing *pointlike* photon γ^* by the *nonpointlike* vector meson *V*. To the leading $\log\frac{1}{x}$, the effect of perturbative higher, $q\bar{q}g$, $q\bar{q}gg$, etc., Fock states in the *pointlike* photon amounts to the BFKL evolution of the color dipole cross section or of the unintegrated gluon SF while retaining the $q\bar{q}$ Fock state approximation [35–37, 129, 161, 162]. Namely, in the DIS counterpart of (72), one calculates the photoabsorption cross section as an expectation value of the dipole cross section over the lowest $q\bar{q}$ state of the photon:

$$\sigma_{\text{tot}}(\gamma^* p) = \int_0^1 dz \int d^2\mathbf{r} \Psi^*_{\gamma^*}(z, \mathbf{r})\sigma_{\text{dip}}(x, \mathbf{r})\Psi_{\gamma^*}(z, \mathbf{r}). \quad (98)$$

4.2. The Helicity and Chiral Structure of the Photon

In the momentum representation, the chiral structure of the $\bar{q}\gamma_\mu q A_\mu$ vertex is as follows. The photon polarization vectors are described in Section 2.3.2; here, we only notice that, in the Sudakov representation,

$$e_\mu(L) = -\frac{1}{Q}\left(q' + \frac{Q^2}{W^2}p'\right), \quad (99)$$

where the two Sudakov light-cone vectors are defined as

$$P = p' + \frac{m_p^2}{W^2}q', \quad q = q' - xP,$$
$$\quad (100)$$
$$q'^2 = p'^2 = 0, \quad x = \frac{Q^2}{W^2} \ll 1.$$

Hereafter, it will be convenient to use twice the quark and antiquark helicity, λ, $\bar{\lambda} = \pm 1$, which should not cause a confusion. For the transverse photons, $\lambda_\gamma = \pm 1$; in the momentum representation, the perturbative QED vertex gives the structure

$$\bar{q}_\lambda\gamma_\mu q_{\bar{\lambda}}e_\mu(\lambda_\gamma) = \frac{1}{\sqrt{z(1-z)}}\{-\sqrt{2}m_f\delta_{\lambda_\gamma,\lambda}\delta_{\lambda,\bar{\lambda}} \\ + 2\delta_{\lambda,-\bar{\lambda}}[z\delta_{\lambda_\gamma,\lambda} - (1-z)\delta_{\lambda_\gamma,\bar{\lambda}}](\mathbf{k}\cdot\mathbf{e}(\lambda_\gamma))\} \quad (101)$$

and for the longitudinal (scalar) photons,

$$\bar{q}_\lambda\gamma_\mu q_{\bar{\lambda}}e_\mu(\lambda_\gamma = 0) = -2Q\sqrt{z(1-z)}\delta_{\lambda,-\bar{\lambda}}. \quad (102)$$

Here, z and $(1 - z)$ are the fractions of the photon's light-cone momentum carried by the quark and antiquark, respectively, and **k** and –**k** are the corresponding transverse momenta. The perturbative chiral-odd component of the transverse photon with parallel helicities vanishes for massless quarks. The scaling contribution to the DIS structure function $F_2(x, Q^2)$ comes from the chiral-even component with antiparallel helicities.

4.3. The Light-Cone Helicity and Chiral Structure of Vector Mesons and Rotation Invariance

In the vector meson, the quark and antiquark are in the spin-triplet state and either *S*- or *D*-wave. The light-cone wave function $\Psi_V(z, \mathbf{p})$ is a probability amplitude for expansion of the vector meson in $q\bar{q}$ states with invariant mass

$$M^2 = \frac{\mathbf{k}^2 + m_f^2}{z(1-z)} = 4(m_f^2 + \mathbf{p}^2). \quad (103)$$

One calculates first the amplitude of production of the $q\bar{q}$ pair,

$$\gamma^* p \longrightarrow (q\bar{q})p', \quad (104)$$

and then projects it onto the vector state by weighting with $\Psi_V(z, \mathbf{k})$ and the relevant helicity factors. The use of the three-dimensional momentum of the quark in the $q\bar{q}$ rest frame, $\mathbf{p} = \left(\mathbf{k}, \left(z - \frac{1}{2}\right)M\right)$,

$$\frac{d^3\mathbf{p}}{M} = \frac{dz d^2\mathbf{k}}{4z(1-z)} \quad (105)$$

is helpful to see a link to the conventional quantum-mechanical description.

The helicity/chiral structure of the vector meson for the widely used $Vq\bar{q}$ extension of the QED vertex of the form

$$V_\mu\bar{q}_f\gamma_\mu q_f\Gamma_V(z, \mathbf{k}) \quad (106)$$

is the same as for the photon subject to the substitution $Q \longrightarrow M$ for the longitudinal vector meson. The vertex (106) gives a certain admixture of the *S* and *D* waves. The *SD*-mixing is familiar from the case of the deuteron, where it originates from the pion-exchange tensor interaction; the presence of the potential-dependent *SD*-mixing in vector mesons is a generic feature of potential models (for the review, see [47]).

The rotation-invariant light-cone description of the pure *S*- and *D*-wave states and the corresponding vertices S_μ and D_μ are found in [54, 171] (for the related discussion, see also [234, 235]). To generate the pure *S*-wave state, one needs to add the generalized Pauli vertex.

Upon applying the Gordon identities, the pure *S*-wave vertex can be cast in the form

$$\Gamma_S(z, \mathbf{k})\bar{q}_f S_\mu q_f V_\mu$$

$$= \Gamma_S(z, \mathbf{k})\bar{q}_f \left\{ \gamma_\mu - \frac{1}{(M+2m)}(p_f - p_{\bar{f}})_\mu \right\} q_f V_\mu \quad (107)$$

with the helicity/chiral structure

$$\bar{q}_\lambda S_\mu q_{\bar{\lambda}} V_\mu(\pm 1) = \frac{1}{\sqrt{z(1-z)}} \left\{ -\sqrt{2} m_f \delta_{\lambda_V, \lambda} \delta_{\lambda, \bar{\lambda}} \right.$$

$$+ 2\delta_{\lambda, -\bar{\lambda}}[z\delta_{\lambda_V, \lambda} - (1-z)\delta_{\lambda_V, \bar{\lambda}}](\mathbf{k} \cdot \mathbf{V}(\lambda_V))$$

$$+ \frac{2(\mathbf{k} \cdot \mathbf{V}(\lambda_V))}{M+2m_f}$$

$$\left. \times [m_f(1-2z)\delta_{\lambda, -\bar{\lambda}} + \sqrt{2}(\mathbf{k} \cdot \mathbf{V}(-\lambda))\delta_{\lambda, \bar{\lambda}}] \right\}, \quad (108)$$

$$\bar{q}_\lambda S_\mu q_{\bar{\lambda}} V_\mu(0) = -2M\sqrt{z(1-z)}\delta_{\lambda, -\bar{\lambda}}$$

$$- \frac{M(1-2z)}{(M+2m_f)\sqrt{z(1-z)}}$$

$$\times [m_f(1-2z)\delta_{\lambda, -\bar{\lambda}} + \sqrt{2}(\mathbf{k} \cdot \mathbf{V}(-\lambda))\delta_{\lambda, \bar{\lambda}}].$$

Note that momenta p_f and $p_{\bar{f}}$ correspond to on-mass-shell fermions (see details in [54]), which justifies the usage of the Gordon identity. The corresponding vertex functions Γ_S will only depend on the "radial" variable M^2 and can be related to the momentum-space radial wave functions $\psi_S(z, \mathbf{k})$:

$$\Gamma_{S, D}(M^2) = \psi_S(z, \mathbf{k})(M^2 - m_V^2). \quad (109)$$

An important part of the rotation-invariant description is that the transversity condition must be imposed at the level of the $q\bar{q}$ pair, which leads to the concept of the *running longitudinal* polarization vector $V_L(M)$, which has the Sudakov expansion

$$V(\lambda_V = 0) = \frac{1}{M}\left(q' - \frac{M^2}{W^2}p'\right), \quad (110)$$

such that it is orthogonal to the 4-momentum of the on-mass-shell $q\bar{q}$ pair, $(v_{q\bar{q}} V_L(M)) = 0$, where

$$v_{q\bar{q}} = q' + \frac{M^2}{W^2}p', \quad v_{q\bar{q}}^2 = M^2. \quad (111)$$

This running polarization vector has been used in (108).

The light-cone extension of the considerations in Section 3.4.1 gives the $V^0 \longrightarrow e^+e^-$ decay constant for the *S*-wave state [54]:

$$g_V = N_c \int \frac{d^3\mathbf{p}}{(2\pi)^3}\psi_S(\mathbf{p})\frac{8}{3}(M+m_f)$$

$$= N_c \int_0^1 dz \int \frac{d^2\mathbf{k}}{(2\pi)^3 z(1-z)}\psi_S(\mathbf{p})\frac{2}{3}M(M+m_f) \quad (112)$$

$$= g_V \int_0^1 dz \phi_V(z),$$

where $\phi_V(z)$ is the so-called distribution amplitude for the pure *S*-wave vector meson. The general phenomenology of distribution amplitudes can be found in [166, 236–238]. If the vector meson is saturated by the $q\bar{q}$ state, then (112) is supplemented by the normalization condition

$$1 = \frac{N_c}{(2\pi)^3}\int d^3\mathbf{p} \, 4M \left|\psi^S(\mathbf{p}^2)\right|^2$$

$$= \frac{N_c}{(2\pi)^3}\int \frac{dz d^2\mathbf{k}}{z(1-z)}M^2 \left|\psi^S(\mathbf{p}^2)\right|^2. \quad (113)$$

The calculations with the fixed longitudinal polarization vector defined for fixed $M = m_V$ break the rotation invariance, which is often the case with parametrizations used in the literature [21, 26, 204, 239–241]. In technical terms, the fixed polarization vector leads to a mixing of the longitudinal spin-1 and spin-0 states. One of the drawbacks of the fixed polarization vector is that the $V \longrightarrow e^+e^-$ decay width would depend on the polarization state of the vector meson, while the rotation-invariant approach with the running longitudinal polarization vector guarantees that the decay constants for the transverse and longitudinal vector mesons are identical. Quite often, in the fixed-polarization vector approaches, the manifestly different radial wave functions are introduced for the transverse and longitudinal vector mesons [181, 205].

The principal effect of the Pauli vertex in the helicity/chiral expansion (108) is the chiral-odd parallel-helicity component of the transverse vector meson, which does not vanish for massless quark. Going back from vector mesons to real photons, Ivanov [242] argued that the related nonperturbative chiral-odd component in the real photon is large. They relate the normalization of this component of the real-photon wave function to the quark condensate and its magnetic susceptibility [243].

4.4. The Impact Factor Representation for the Helicity Amplitudes

The $k_\perp$-factorization, or impact factor, representation for the vector meson production closely repeats that for the Compton scattering amplitude in the case of DIS [37, 168]. The three changes are that, now, the momentum transfer $\Delta \neq 0$, the vertex function for the

S-wave vector meson is different from the γ_μ vertex (104) for the photon, and the conventional unintegrated gluon SF which describes the t-channel exchange is replaced by the off-forward (skewed) unintegrated gluon structure function of the target, $\mathcal{F}(x_1, x_2, \boldsymbol{\kappa}_1, \boldsymbol{\kappa}_2)$. Here,

$$x_1 \approx \frac{Q^2 + M_1^2}{W^2}, \quad x_2 \approx \frac{M_1^2 - m_V^2}{W^2}, \qquad (114)$$

and M_1 are the invariant mass of the intermediate $q\bar{q}$ pair (for the kinematical variables, see Fig. 16).

The imaginary part of the total amplitude can be written as [54, 171]

$$\mathrm{Im}\,\mathcal{T} = W^2 \frac{c_V \sqrt{4\pi\alpha_{em}}}{4\pi^2} \int \frac{d^2\boldsymbol{\kappa}}{\boldsymbol{\kappa}^4} \alpha_S(\max\{\boldsymbol{\kappa}^2, \varepsilon^2 + \mathbf{k}^2\}) \qquad (115)$$

$$\times \mathcal{F}(x_1, x_2, \boldsymbol{\kappa}_1, \boldsymbol{\kappa}_2) \int \frac{dz\, d^2\mathbf{k}}{z(1-z)} I(\lambda_V, \lambda_\gamma),$$

where, for the pure S-wave vector mesons, the integrands $I(\lambda_V, \lambda_\gamma)$ have the form

$$I^S(L, L)$$
$$= 4QM z^2 (1-z)^2 \left[1 + \frac{(1-2z)^2}{4z(1-z)} \frac{2m_f}{M + 2m_f} \right] \Psi_2^* \Phi_2, \qquad (116)$$

$$I^S(T, T)_{\lambda_V = \lambda_\gamma}$$
$$= m_f^2 \Psi_2^* \Phi_2 + [z^2 + (1-z)^2](\boldsymbol{\Psi}_1^* \cdot \boldsymbol{\Phi}_1) \qquad (117)$$
$$+ \frac{m_f}{M + 2m_f} [(\mathbf{k} \cdot \boldsymbol{\Psi}_1^*)\Phi_2 - (2z-1)^2 (\mathbf{k} \cdot \boldsymbol{\Phi}_1)\Psi_2^*],$$

$$I^S(T, T)_{\lambda_V = -\lambda_\gamma} = 2z(1-z)(\Phi_{1x}\Psi_{1x}^* - \Phi_{1y}\Psi_{1y}^*)$$
$$- \frac{m_f}{M + 2m_f}[(k_x\Psi_{1x}^* - k_y\Psi_{1y}^*)\Phi_2 \qquad (118)$$
$$- (2z-1)^2(k_x\Phi_{1x} - k_y\Phi_{1y})\Psi_2^*],$$

$$I^S(L, T) = -2Mz(1-z)(2z-1)(\mathbf{e}\boldsymbol{\Phi}_1)\Psi_2^*$$
$$\times \left[1 + \frac{(1-2z)^2}{4z(1-z)} \frac{2m_f}{M + 2m_f} \right] \qquad (119)$$
$$+ \frac{Mm_f}{M + 2m_f}(2z-1)(\mathbf{e}\boldsymbol{\Psi}_1^*)\Phi_2,$$

$$I^S(T, L) = -2Qz(1-z)(2z-1)$$
$$\times \left[(\mathbf{V}^*\boldsymbol{\Psi}_1^*)\Phi_2 - \frac{2m_f}{M + 2m_f}(\mathbf{V}^*\mathbf{k})\Psi_2^*\Phi_2 \right]. \qquad (120)$$

Here, $\mathbf{r} = \mathbf{k} + \left(z - \frac{1}{2}\right)\boldsymbol{\Delta}$, and

Fig. 16. The kinematical variables entering the $k_\perp$-factorization representation (116) for vector meson production amplitudes.

$$\Phi_2 = -\frac{1}{(\mathbf{r} + \mathbf{k})^2 + \varepsilon^2} - \frac{1}{(\mathbf{r} - \mathbf{k})^2 + \varepsilon^2}$$
$$+ \frac{1}{(\mathbf{r} + \boldsymbol{\Delta}/2)^2 + \varepsilon^2} + \frac{1}{(\mathbf{r} - \boldsymbol{\Delta}/2)^2 + \varepsilon^2}, \qquad (121)$$

$$\boldsymbol{\Phi}_1 = -\frac{\mathbf{r} + \mathbf{k}}{(\mathbf{r} + \mathbf{k})^2 + \varepsilon^2} - \frac{\mathbf{r} - \mathbf{k}}{(\mathbf{r} - \mathbf{k})^2 + \varepsilon^2}$$
$$+ \frac{\mathbf{r} + \boldsymbol{\Delta}/2}{(\mathbf{r} + \boldsymbol{\Delta}/2)^2 + \varepsilon^2} + \frac{\mathbf{r} - \boldsymbol{\Delta}/2}{(\mathbf{r} - \boldsymbol{\Delta}/2)^2 + \varepsilon^2} \qquad (122)$$

for the definition of ε^2 (see Eq. (77)). Here, $1/(\mathbf{k}^2 + \varepsilon^2)$ and $\Psi_2 \equiv \psi_V(z, \mathbf{k})$ describe transitions into the $\bar{q}$ states with the sum of helicities of the quark and antiquark $\lambda + \bar{\lambda} = \lambda_{\gamma^*, \lambda_V}$, whereas $\mathbf{k}/(\mathbf{k}^2 + \varepsilon^2)$ and $\boldsymbol{\Psi}_1 \equiv \mathbf{k}\psi_V(z, \mathbf{k})$ describe transitions of transverse and vector meson into the $\bar{q}$ states with $\lambda + \bar{\lambda} = 0$, in which the helicity of the photon and vector meson is carried by the orbital angular momentum in the $q\bar{q}$ state.

In the calculation of the double helicity-flip amplitude (118), the x-axis is chosen along the momentum transfer $\boldsymbol{\Delta}$. The point made in Section 3.4.4 that the helicity flip proceeds via the intermediate state with $\lambda + \bar{\lambda} = 0$ is manifest in (117)–(119). The corresponding integrands for the D-wave states can be found in [171].

The z-dependence of the integrands shows that the endpoint contributions ($z \ll 1$ or $1 - z \ll 1$) are suppressed in the longitudinal amplitude $\mathcal{T}(L, L)$ already in the integrands, while, for the other helicity amplitudes, this suppression comes from the wave functions (see discussion in Sections 4.7 and 4.9 below). The factor $(2z - 1)$ in the integrands of the helicity-flip amplitudes $\mathcal{T}(L, T)$ and $\mathcal{T}(T, L)$ corresponds to the longitudinal Fermi momentum of quarks in the vector meson, which makes manifest the relativistic origin of helicity
Fig. 17. The sequential splitting of gluons in the Feynman diagram (a) for production of the multigluon final state viewed as a random walk in the impact parameter space of gluons from the $q\bar{q}$ pair of the photon γ^* to the proton target.

flip. The expected hierarchy of the helicity flip amplitudes is as follows [170, 212]. Roughly,

$$\frac{|\mathcal{T}_{01}|}{\sqrt{|\mathcal{T}_{11}|^2 + |\mathcal{T}_{00}|^2}} \sim \frac{\sqrt{|t|}}{\sqrt{Q^2 + m_V^2}}, \tag{123}$$

$$\frac{|\mathcal{T}_{10}|}{\sqrt{|\mathcal{T}_{11}|^2 + |\mathcal{T}_{00}|^2}} \sim \frac{\sqrt{|t|}}{\sqrt{Q^2 + m_V^2}} \frac{Q m_V}{Q^2 + m_V^2}, \tag{124}$$

$$\frac{|\mathcal{T}_{1-1}|}{\sqrt{|\mathcal{T}_{11}|^2 + |\mathcal{T}_{00}|^2}} \sim \frac{|t|}{m_V \sqrt{Q^2 + m_V^2}}. \tag{125}$$

For heavy flavor vector mesons, the helicity flip amplitudes are expected to be further suppressed by the nonrelativistic Fermi motion.

The real part of the amplitude can be reconstructed from the imaginary part using the derivative analyticity relation [244, 245]:

$$\text{Re} \frac{\mathcal{T}}{W^2} = \frac{\pi}{2} \frac{\partial}{\partial \log W^2} \text{Im} \frac{\mathcal{T}}{W^2}. \tag{126}$$

4.5. The Off-Forward Unintegrated Gluon Density: the Δ-Dependence within the Diffraction Cone and the BFKL Pomeron Trajectory

Thanks to a large amount of high-precision data on F_{2p} both in the soft and hard regimes, the simple, ready-to-use parametrizations for the forward unintegrated gluon density $\mathcal{F}(x, \kappa^2)$ are now available [34]. These parametrizations can be exploited in different high-energy reactions and bring the gluon density of the proton under control.

For the practical application of the formalism of Section 4.4, one needs the off-forward unintegrated gluon distribution $\mathcal{F}\left(x_1, x_2, \kappa + \frac{1}{2}\Delta, -\kappa + \frac{1}{2}\Delta\right)$. Its dependence on the momentum transfer Δ comes from two courses. The first one is the soft quantity that can

be dubbed the two-gluon form factor of the proton. The second is the Δ-dependence of the BFKL two-gluon ladder. When viewed in the impact parameter space, at each splitting of the gluon into two gluons, $g \longrightarrow gg$, the hard gluon, which carries the large longitudinal momentum of the parent gluon, emerges at the same impact parameter as the parent gluon, whereas the soft one, which carries small longitudinal momentum, emerges at an impact parameter $|\Delta \mathbf{b}_i| \sim \frac{1}{|\kappa_i|}$ from the parent gluon. Consequently, as illustrated in Fig. 17, the splitting of gluons in the process of the $\log \frac{1}{x}$ evolution is accompanied by the Gribov–Feinberg–Chernavski random walk [246, 247] of small-x gluons to larger and larger impact parameters **b**. The asymptotic freedom, i.e., the running α_S, enhances the role of large random walks of the order of the perturbative gluon propagation radius R_c. This suggests that, $\langle \mathbf{b}^2 \rangle$, will rise proportionally to the number of gluon splittings, i.e.,

$$\langle \mathbf{b}^2 \rangle \propto R_c^2 \log \frac{1}{x} \propto R_c^2 \log W^2. \tag{127}$$

In conjunction with the Regge formula (37) and the definition (43), this entails the finite slope α'_{BFKL} of the Regge trajectory of the hard BFKL Pomeron. Evidently, the dimensionfull α'_{BFKL} is the soft parameter, and as such it depends manifestly on the infrared regularization of QCD. The solution of the color dipole BFKL equation with Yukawa-type cutoff and infrared freezing of α_S gave $\alpha'_{\text{BFKL}} = 0.12$–$0.15$ GeV^{-2} [25, 134, 248]. The results for the shrinkage rate α'_{BFKL} depend on the admixture of subleading BFKL poles and exhibit weak dependence on κ^2. The quoted value is found for the specific boundary condition, which gives a good description of the HERA results on the proton structure function [134, 136].

When viewed in the momentum space, the same Gribov–Feinberg–Chernavski diffusion suggests the weakening of the κ–Δ correlation with the number of splittings. Indeed, Balitsky and Lipatov have shown that the dependence of the off-forward gluon density $(\kappa \cdot \Delta)$ corresponds to subleading singularities [37, 127] and, arguably, can be neglected for HERA energy range.

Consequently, for small momentum transfers within the diffraction cone, the Δ-dependence can be factored out as

$$\mathcal{F}\left(x_1, x_2, \kappa + \frac{1}{2}\Delta, -\kappa + \frac{1}{2}\Delta\right)$$
$$= \mathcal{F}(x_1, x_2, \kappa, -\kappa) \exp\left(-\frac{b_{3P}\Delta^2}{2}\right). \tag{128}$$

We parametrize b_{3P} as

$$b_{3P} = b_{2G} + 2\alpha'_{\text{BFKL}} \log \frac{W^2 x_0}{Q^2 + m_V^2}, \qquad (129)$$

where the soft parameter b_{2G} can be regarded as a slope of the form factor of the proton as probed by the color singlet two-gluon state. In principle, one can determine it experimentally isolating the BFKL contribution to diffractive DIS into high-mass states. Strictly speaking, this parameter b_{2G} as well as the Pomeron slope α' can change from the soft, nonperturbative, to hard, BFKL, gluon density, taking [54, 55] the universal parameters, $b_{2G} = B_N = 4 \text{ GeV}^{-2}$ with $x_0 = 3.4 \times 10^{-4}$ and the $\boldsymbol{\kappa}^2$-independent $\alpha_P^{\text{soft}} = \alpha'_{\text{BFKL}} = 0.25 \text{ GeV}^{-2}$ is the poor man's approximation.

4.6. The Off-Forward Unintegrated Gluon Density: The Dependence on Skewness

Bartels was the first to observe [249] that two gluons enter the amplitude at $x_2 \neq x_1 \approx x$, because the invariant mass squared M_1^2 of the intermediate $q\bar{q}$ system is close to $M^2 \approx m_V^2$ for the final $q\bar{q}$ state and is far from the virtuality of the incident photon $-Q^2$. Such a skewed unintegrated gluon density can be, in principle, accessed in DVCS [31], but that is not yet a practical solution. Shuvaev *et al.* [250] and Radyushkin [251] argued that, at small x, the skewed distribution can be related to the conventional one: if $\mathscr{F} \propto x^{-\lambda}$, then

$$\mathscr{F}(x_1, x_2 \ll x_1, \boldsymbol{\kappa}, -\boldsymbol{\kappa}) = R_g \mathscr{F}(x_1, \boldsymbol{\kappa}),$$

$$R_g = \frac{2^{2\lambda + 3}}{\sqrt{\pi}} \frac{\Gamma\left(\lambda + \frac{5}{2}\right)}{\Gamma(\lambda + 4)}. \qquad (130)$$

The above factor R_g can be effectively accounted for in a form of the x-rescaling

$$R_g \left(\frac{1}{x_1}\right)^\lambda = \left(\frac{1}{c(\lambda) x_1}\right)^\lambda, \qquad (131)$$

where $c(\lambda)$ changes from ≈ 0.435 at $\lambda = 0$ to 0.4 at $\lambda = 1$. Given this very flat dependence, one can take fixed $c = 0.41$, so that

$$\mathscr{F}(x, 0, \boldsymbol{\kappa}, -\boldsymbol{\kappa}) \approx \mathscr{F}(cx, \boldsymbol{\kappa}). \qquad (132)$$

Hereafter, we approximate the skewed gluon density by the forward density take at

$$x_g = cx_1 = c \frac{Q^2 + m_V^2}{W^2}. \qquad (133)$$

Of course, once this rescaling of x is implemented, and the Fourier transform to the color dipole representation is performed starting from Eqs. (115)–(120), the

color dipole and $k_\perp$-factorization approaches will be identical to each other.

4.7. The Ansatz for the Wave Function

For the heavy quarkonia, a good insight into the functional form of the radial wave function (WF) $\psi_V(\mathbf{p}^2)$ comes from the potential model calculations [47, 48]. Here, at least for the $\Upsilon(1S)$, the role of the QCD Coulomb interaction is substantial. It is less so for the charmonium, where the gross properties of lighter vector mesons, which have a large size, are entirely controlled by the confining interaction, and, here, one is bound to the model parametrizations [54]. The popular harmonic oscillator WF emphasizes the confinement property; it decreases steeply at large $\mathbf{p}^2$:

$$\psi_{1S} = c_1 \exp\left(-\frac{\mathbf{p}^2 a_1^2}{2}\right),$$

$$\psi_{2S} = c_2 (\xi_{\text{node}} - \mathbf{p}^2 a_2^2) \exp\left(-\frac{\mathbf{p}^2 a_2^2}{2}\right), \qquad (134)$$

which emphasizes the contrast between the nonpointlike vector meson and pointlike photon for which $\Gamma_{\gamma^*}(z, \mathbf{k}) = \sqrt{4\pi\alpha_{em}} = \text{const}$. The position of the node, ξ_{node}, is fixed from the orthogonality condition. The attractive pQCD Coulomb interaction between the quark and antiquark enhances the WF at small $\mathscr{R}_{q\bar{q}}$ and/or large relative momentum; the minimal relativization of the familiar Coulomb WF suggests

$$\psi_{1S}(\mathbf{p}^2) = \frac{c_1}{\sqrt{M}} \frac{1}{(1 + a_1^2 \mathbf{p}^2)^2},$$

$$\psi_{2S}(\mathbf{p}^2) = \frac{c_2}{\sqrt{M}} \frac{(\xi_{\text{node}} - a_2^2 \mathbf{p}^2)}{(1 + a_2^2 \mathbf{p}^2)^3}, \qquad (135)$$

which decreases as an inverse power of $\mathbf{p}^2$ much slower than (134). The factor $1/\sqrt{M}$ in (135) is a model-dependent suppression to make the decay constant (112) convergent. Arguably, those two extreme ansatzes give a good idea on the model dependence of vector meson production amplitudes. The radius a_1 and the normalization c_1 are fixed by the $V_0 \longrightarrow e^+ e^-$ decay constant (112) and the normalization condition (113). The hybrid model in which the short-distance QCD Coulomb interaction in light vector mesons has been treated perturbatively is found in [21, 49].

4.8. The Hard Scale $\overline{Q}^2$: the Link to the Leading $\log Q^2$-Approximation and the Exponent of the W-Dependence

For soft gluons,

$$\boldsymbol{\kappa}^2 \ll (\varepsilon^2 + \mathbf{k}^2) = z(1 - z)(Q^2 + M^2) \qquad (136)$$

one can expand Φ_2 and Φ_1 as [252] (for the sake of simplicity, we consider $\Delta = 0$):

$$\Phi_2 \approx \frac{2(\varepsilon^2 - \mathbf{k}^2)}{(\varepsilon^2 + \mathbf{k}^2)^3}\boldsymbol{\kappa}^2$$

$$= \frac{2}{z^2(1-z)^2(Q^2+M^2)^2}\left[1 - \frac{2\mathbf{k}^2}{z(1-z)(Q^2+M^2)}\right]\boldsymbol{\kappa}^2, \quad (137)$$

$$\Phi_1 \approx \frac{4\varepsilon^2\mathbf{k}}{(\varepsilon^2 + \mathbf{k}^2)^3}\boldsymbol{\kappa}^2$$

$$= \frac{4\mathbf{k}}{z^2(1-z)^2(Q^2+M^2)^2}\left[1 - \frac{\mathbf{k}^2}{z(1-z)(Q^2+M^2)}\right]\boldsymbol{\kappa}^2. \quad (138)$$

A natural approximation is $M^2 \approx m_V^2$. Then, the factor $(Q^2 + m_V^2)^{-2}$ which emerges in (137) and (138) corresponds to the factor precisely r_S^4 of the color dipole approach (see Eqs. (78) and (79)). The determination of the hard scale in the gluon SF is a bit more subtle.

Expansions (137) and (138) define the leading $\log \overline{Q}^2$ contribution with logarithmic integration over $\boldsymbol{\kappa}^2$:

$$\int\limits_0^{z(1-z)(Q^2+M^2)} \frac{d\boldsymbol{\kappa}^2}{\boldsymbol{\kappa}^2}\mathscr{F}(x_g, \boldsymbol{\kappa}) \quad (139)$$

$$= G(x_g, z(1-z)(Q^2+M^2)).$$

The emerging running hard scale depends on z and M^2; for the heavy quarkonia, the wave function of the vector meson is peaked at $z \sim \frac{1}{2}$, and one can take $M^2 \approx m_V^2$, consequently, $z(1-z)(Q^2+M^2) = \overline{Q}^2$ of Eq. (9).

The contribution from small dipoles, $r < r_S$, or from hard gluons beyond the leading $\log \overline{Q}^2$ domain, $\boldsymbol{\kappa}^2 \gtrsim \overline{Q}^2$, is an integral part of the $k_\perp$-factorization approach [21, 33, 34]. In this region,

$$\Phi_2 \approx \frac{2}{(\varepsilon^2 + \mathbf{k}^2)}, \quad \Phi_1 \approx \frac{2\mathbf{k}}{(\varepsilon^2 + \mathbf{k}^2)}, \quad (140)$$

and the correction to the leading $\log \overline{Q}^2$ result (139) can be cast as (see also [173])

$$\overline{Q}^2 \int\limits_{\overline{Q}^2} \frac{d\boldsymbol{\kappa}^2}{(\boldsymbol{\kappa}^2)^2}\mathscr{F}(x_g, \boldsymbol{\kappa}) \approx \mathscr{F}(x_g, \overline{Q}^2)\log C_g, \quad (141)$$

where $\log C_g \sim 1$ and depends on the exact $\boldsymbol{\kappa}^2$-dependence of $\mathscr{F}(x_g, \boldsymbol{\kappa})$. Following [33, 34] one can combine (139) and (141) as

$$G(x_g, \overline{Q}^2) + \mathscr{F}(x_g, \overline{Q}^2)\log C_g \approx G(x_g, C_g\overline{Q}^2). \quad (142)$$

Consequently, the gluon density is mapped at hard

$$\overline{Q}_G^2 = C_g\overline{Q}^2, \quad (143)$$

which is slightly different from $\overline{Q}^2$. As already mentioned above, $I^S(L, L)$ of (116) is more peaked at $z \sim \frac{1}{2}$, whereas $I^S(T, T)_{\lambda_V = \lambda_\gamma}$ of (117) extends more to the endpoints $z \sim 0$ and $z \sim 1$. This leads to an inequality $\overline{Q}_{GL}^2 > \overline{Q}_{GT}^2$ and implies that the typical dipole sizes in the $T \longrightarrow T$ amplitude are somewhat larger than for the $L \longrightarrow L$ amplitude.

For a more quantitative analysis, the $\boldsymbol{\kappa}^2$-integrations can be cast in the form

$$\frac{1}{W^2}\mathrm{Im}\,\mathscr{T}_{LL, TT} \equiv \int \frac{d\vec{\boldsymbol{\kappa}}^2}{\vec{\boldsymbol{\kappa}}^2}\mathscr{F}(x_g, \vec{\boldsymbol{\kappa}})W_{L, T}(Q^2, \boldsymbol{\kappa}^2)$$

$$\equiv W_{L, T}(Q^2, 0)G(x_g, \overline{Q}_{GL, GT}^2). \quad (144)$$

The typical behavior of normalized weight functions $W_{L, T}(Q^2, \vec{\boldsymbol{\kappa}}^2)/W_{L, T}(Q^2, 0)$ is shown in Fig. 18, and, for smooth $\mathscr{F}(x_g, \boldsymbol{\kappa}^2)$, they can be approximated by the step-function $\theta(\overline{Q}_{GL, GT}^2 - \boldsymbol{\kappa}^2)$, where $\overline{Q}_{GL, GT}^2$ are defined by the median, $W_{L, T}(Q^2, \overline{Q}_{GL, GT}^2) = \frac{1}{2}W_{L, T}(Q^2, 0)$, the results are close to the ones found in [21]. At moderately large Q^2, the strong scaling violations in $\mathscr{F}(x_g, \boldsymbol{\kappa}^2)$ shown in Fig. 10 have a strong impact on $\overline{Q}_{GL, GT}^2$ as shown in Fig. 19. The inequality $\overline{Q}_{GL}^2 > \overline{Q}_{GT}^2$ found in [21] is retained, and the hierarchy of $\overline{Q}_{GL, GT}^2$ from light to heavy flavors is the same as of $\overline{Q}^2$.

This affect of $\overline{Q}_{GL}^2 > \overline{Q}_{GT}^2$ is demonstrated in Fig. 20 on an example of $G(x_g, Q_{GT}^2)$ and $G(x_g, Q_{GL}^2)$ for the ρ production: the finding of $G(x_g, Q_{GL}^2) > G(x_g, Q_{GT}^2)$ reflects the inequality $\overline{Q}_{GL}^2 > \overline{Q}_{GT}^2$ at equal Q^2. For the same reason, different helicity amplitudes can have slightly different energy dependence. The effect of different scales diminishes at larger Q^2 with weakening scaling violations (see Fig. 10).

A tricky point is that the small-$\boldsymbol{\kappa}$ expansion for the double-flip amplitude starts with the constant, and it is dominated by the soft-gluon exchange, the term $\propto \boldsymbol{\kappa}^2$ is of higher twist [170, 212].
Fig. 18. The normalized weight functions $W_L(Q^2, \vec{\kappa}^2)/W_L(0)$ and $W_T(Q^2, \vec{\kappa}^2)/W_T(0)$ for the ρ production calculated at $Q^2 = 100\ \mathrm{GeV}^2$ in the $k_\perp$-factorization approach [38].

Of course, the above separation into the leading $\log \overline{Q}^2$ and hard regions is redundant when either the color dipole and the full-fledged $k_\perp$-factorization approaches are used. The $k_\perp$-factorization analysis reveals somewhat better the role of $\mathbf{k}^2$ in (136) for the determination of the leading $\log \overline{Q}^2$ region. One may recall that the inclusion of the Fermi motion effects [239], is automatically contained in the color dipole calculations and should not be discussed separately. The specific form of the Fermi motion correction suggested by Frankfurt *et al.* [239] is not borne out by the $k_\perp$-factorization analysis, though.

Finally, Eq. (144) clearly shows that the energy dependence of the production amplitude is controlled by the x_g-dependence of the integrated gluon density, i.e., by the effective intercept $\lambda(\overline{Q}^2_{GL,\,GT})$ defined in Section 3.3.1:

$$\mathrm{Im}\,\mathcal{T}(W^2, t = 0)_{LL,\,TT} \propto \left(\frac{1}{x}\right)^{1 + \lambda(\overline{Q}^2_{GL,\,GT})} \tag{145}$$

$$\propto (W^2)^{1 + \lambda(\overline{Q}^2_{GL,\,GT})}.$$

4.9. The Production Amplitude and the Vector Meson Distribution Amplitude

At large Q^2, there emerges one useful approximation usually referred to as the collinear approximation. Specifically, here, the explicit $\mathbf{k}^2$-dependence in $\overline{Q}^2$ is neglected, and the $d^2\mathbf{k}$ integration can be factored out. In the color dipole language, this amounts to neglecting the r-dependence of the vector meson wave function and taking it at $r = 0$, but keeping its z-dependence. The results are best seen in the momentum representation. For instance, the factor $z^2(1 - z)^2$ in $I^S(L, L)$ (Eq. (117)) cancels the factor $z^{-2}(1 - z)^{-2}$ in Eq. (137) for Φ_2, and the vector meson wave function enters $\mathcal{T}_{LL}$ in the form of an integral

$$\int\limits^{\mathbf{k}^2 < \overline{Q}^2} d^2\mathbf{k}\, M \psi_V^*(z, \mathbf{k})\left[1 + \frac{(1 - 2z)^2}{4z(1 - z)}\frac{2m_f}{M + 2m_f}\right], \tag{146}$$

which is very similar to the distribution amplitude defined by (112) at the factorization scale $\overline{Q}^2$. We emphasize that the factor in the square brackets in (146) depends on the *SD*-wave mixing. For the nonrelativistic

Fig. 19. The scales $\overline{Q}^2_{GL,\,GT}$ at which the ρ production maps the gluon density as a function of Q^2, found in the $k_\perp$-factorization approach [38]. Shown also is the heavy flavor approximation $\overline{Q}^2_G = \overline{Q}^2 = \frac{1}{4}(Q^2 + m_\rho^2)$.
$G(X_q, Q_p^2)$

Fig. 20. The effect of different hard scales on the integrated gluon density (142) which enters the dominant SCHC amplitudes $\mathcal{T}_{LL}$ and $\mathcal{T}_{TT}$ for the ρ production as found in the $k_\perp$-factorization approach [55].

heavy quarkonia $M \approx m_V$, $z \approx \dfrac{1}{2}$, the proportionality of the two quantities is exact, and one finds (cf. (68))

$$\frac{d\sigma_L}{d|t|}\bigg|_{t=0} = \frac{\pi^3}{12\alpha_{em}} \frac{Q^2}{\overline{Q}^8} m_V \Gamma(V \longrightarrow e^+ e^-) \tag{147}$$
$$\times [\alpha_s(\overline{Q}^2) G(x_g, \overline{Q}_G^2)]^2$$

and

$$R_V = \frac{\sigma_L(\gamma^* p \longrightarrow Vp)}{\sigma_T(\gamma^* p \longrightarrow Vp)} \approx \frac{Q^2}{m_V^2} R_{LT} \tag{148}$$

with $R_{LT} = 1$ if the slight possible difference of the t-dependence for the L and T cross sections is neglected. Since the proportionality $R_V \propto Q^2$ at small Q^2 is a generic consequence of the electromagnetic gauge invariance, the true dynamical features of vector meson production are manifested by the departure of R_{LT} from unity. We strongly advocate the representation of the experimental data in terms of this parameter.

4.10. The Ratio $R = \sigma_L/\sigma_T$ and Short-Distance Properties of Vector Mesons

One word of caution on the ratio (148) is in order [253]. In the Introduction, we emphasized how the vector meson production $\gamma^* p \longrightarrow Vp$ is obtained by analytic continuation from the elastic Compton scattering $\gamma^* p \longrightarrow \gamma^* p$. In the course of this analytic continuation, one changes from the pointlike $\gamma^* q\bar{q}$ to the nonpointlike $Vq\bar{q}$ vertex.

Making use of the optical theorem for the Compton scattering, one finds

$$R_{\text{Compton}} = \left| \frac{A(\gamma_L^* p \longrightarrow \gamma_L^* p)}{A(\gamma_T^* p \longrightarrow \gamma_T^* p)} \right|^2$$
$$= \left(\frac{\sigma_L(\gamma^* p)}{\sigma_T(\gamma^* p)} \right)^2 = R_{\text{DIS}}^2 \approx 4 \times 10^{-2}. \tag{149}$$

Here, we used the prediction in [135] for inclusive DIS $R_{\text{DIS}} = \sigma_L(\gamma^* p)/\sigma_T(\gamma^* p) \approx 0.2$, which is consistent with the indirect experimental evaluations at HERA [254]. This result $R_{\text{Compton}} \ll 1$ for the elastic scattering of pointlike photons $\gamma^* p \longrightarrow \gamma^* p$ must be contrasted to $R_V \sim Q^2/m_V^2 \gg 1$ when the pointlike γ^* in the final state is swapped for the nonpointlike vector meson. Evidently, the predictions for R_V are extremely sensitive to the presence of light vector mesons of quasipointlike $q\bar{q}$ component with the WF concentrated at short $q\bar{q}$ separation. The crude model estimates in [21, 49] suggest that modifications of the wave function by attractive short-distance pQCD interaction do indeed lower the theoretical results for R_V.

Here, we just recall the pQCD radiative correction to the Weisskopf–van Royen nonrelativistic approximation (65) for the leptonic decay width [255] (see also [256])

$$\Gamma(V^0 \longrightarrow e^+ e^-)$$
$$= \frac{4\alpha_{em}^2 c_V^2}{m_V^2} |\Psi_V(0)|^2 \left(1 - \frac{8}{3\pi} \alpha_S(m_f) \right)^2, \tag{150}$$

which even for the J/Ψ suppresses the decay width by a factor of ~2. Remarkably, this particular NLO correction is of Abelian nature: it derives from the Karplus–Klein QED radiative correction by a substitution $\alpha_{em} \longrightarrow C_F \alpha_S(m_f^2)$. In the LO approach, the conservative radii of vector mesons are fixed from Eq. (112) without allowance for the pQCD correction (150). Although formula (150) cannot be directly applied to light vector mesons, it is reasonable to wonder what will happen to the vector meson production phenomenology if the Celmaster and Barbieri *et al.* correction for the ρ meson were a factor of 3. To a crude approximation, that will enhance the wave function at the origin by the factor $\approx \sqrt{3}$ and decrease the radius of the vector meson by the factor $\approx 3^{1/3} = 1.44$, which is not off-scale. We expect a substantial reduction of the predicted $R_V = \sigma_L/\sigma_T$ for such a squeezed ρ-meson.

4.11. Perturbative QCD Calculations at High t

Vector meson production at large $|t|$ is believed to be dominated by small impact parameters $b \sim 1/\sqrt{|t|}$. Simultaneously, the large $|t|$ is expected to select the small-size configurations in the $\gamma^* V$ transition vertex. Consequently, at $|t|$ such that $1/\sqrt{|t|} \ll r_S$, i.e., $|t| \gg \overline{Q}^2$,

it becomes the hard pQCD scale for the process. Arguably, in the real photoproduction of heavy flavor mesons, the correct hard scale is $|t| + m_V^2$.

Which $|t|$ is large enough for $|t|$ or $|t| + m_V^2$ to become the hard pQCD scale? That can be decided only *a posteriori*, the answer depends on the normalization of the hard pQCD amplitude and on how fast the soft amplitudes do vanish at large Δ [46]. The large-t data taken at HERA correspond to the Regge regime of $|t| \ll W^2$. In the real photoproduction, one starts with the typical hadronic $\gamma \longrightarrow V$ transition, and our experience with large-t hadronic reactions is a very discouraging one. At small t, within the diffraction cone, the differential cross sections have the $\exp(-B|t|)$ behavior, but at larger $t > 1$ GeV^2, the slowly decreasing multiple-Pomeron exchanges take over: the n-Pomeron exchange gives the t-dependence $\propto \exp\left(-\dfrac{B}{n}|t|\right)$ (for the review and references, see [93]). It is fair to say that the unequivocal evidence for hard pQCD mechanism in high-energy elastic proton–proton scattering is as of yet missing, the soft double-Pomeron mechanism dominates for t of several GeV^2 quite irrespective of the specific model for the soft-Pomeron amplitude (for the recent fits to elastic pp scattering, see [257]). The model-dependent estimates show that the rate of decrease of the soft amplitude slows down dramatically at large $|t|$. For instance, in $\pi\pi$ elastic scattering at moderate energies, the dominance of the hard pQCD amplitude requires $|t| \gtrsim 4$ GeV^2 [258]. The modern handbag mechanism for large-t two-body reactions, as well as electromagnetic form factors of nucleons and pions, relies on soft wave functions of hadrons ([259] and references therein).

Under these circumstances, the single-BFKL Pomeron exchange interpretation of the large-t vector meson data is at best the poor man's approximation. Under this very strong assumption of two-gluon tower exchange, the $k_\perp$-factorization formalism expounded in Section 4.4 is perfectly applicable at large $|t|$. The approximation of Section 4.5 for the unintegrated gluon density is only applicable within the diffraction cone, $\Delta^2 R_c^2 \lesssim 1$, and must be modified.

The available experimental data at large $|t|$ are for the proton dissociate photoproduction $\gamma p \longrightarrow V(\Delta)Y$, which, at large t, can be described in the equivalent parton approximation of Ginzburg *et al.* [30]:

$$\frac{d\sigma_V(\gamma^* p \longrightarrow VY)}{dt\,dx'}$$
$$= \left(\frac{81}{16}g(x', |t|) + \sum_f [q(x', |t|) + \bar{q}(x', |t|)]\right) \quad (151)$$
$$\times \frac{d\sigma_V(\gamma^* q \longrightarrow Vq')}{dt},$$

where $x' = |t|/(m_Y^2 + |t|)$ is the fraction of proton's light-cone momentum carried by the struck parton. It is reminiscent of the familiar collinear factorization, but, in the calculation of the hard cross section, $d\sigma_V(\gamma^* q \longrightarrow Vq')/dt$, the exchange by soft gluons with the momentum $|\kappa| \ll |\Delta|$ must not be included. For instance, in a splitting $q \longrightarrow q'g$ with the $q' - g$ relative transverse momentum **p**, the transverse size of the $q'g$ pair is $r_{q'g} \sim 1/|\mathbf{p}|$. The exchanged gluons with the wavelength $\lambda = 1/|\kappa| \gg r_{q'g}$ cannot resolve such a pair which will act as a pointlike color triplet state indistinguishable from the parent quark q.

The first application of (151) by Ginzburg *et al.* was to the process $\gamma\gamma \longrightarrow VY$ treated in the two-gluon exchange approximation. In the more advanced BFKL approach, this constraint amounts to endowing the target partons in (151) by a t-dependent nonpointlike structure; the practical prescription has been developed by Forshaw and Ryskin [53] (see also [260]).

Notice that $W_{\gamma q}^2 = x' W_{\gamma p}^2$, and the Regge parameter for $\gamma^* q \longrightarrow Vq'$ is

$$\exp(\Delta\eta) = \frac{x' W^2}{m_V^2 - t}, \quad (152)$$

where $\Delta\eta$ is the rapidity gap between the produced vector meson and the hadronic debris of the proton. The lower limit of the x'-integration, $x_{\min} < x' < 1$, is set by the experimental cuts.

Hereafter, we focus on real photoproduction. Beyond the leading-order pQCD, the only working approximations for $\mathscr{F}\left(x_1, x_2, \kappa + \frac{1}{2}\Delta, -\kappa + \frac{1}{2}\Delta\right)$ in the large-Δ regime is based on the Lipatov's solution of the leading-order BFKL equation in the scaling approximation $\alpha_S = $ const. In contrast to the cases of DIS or diffractive vector mesons at small Δ, where the BFKL evolution from the proton side starts from the soft scale and becomes hard only on the virtual photon end of the gluon ladder; at large $|t|$, the large momentum transfer Δ flows along the whole ladder which may make Lipatov's scaling approximation better applicable at large $|t|$. An important point is that, at large Δ, the $\Delta - \kappa$ correlation in $\mathscr{F}\left(x_1, x_2, \kappa + \frac{1}{2}\Delta, -\kappa + \frac{1}{2}\Delta\right)$ becomes very important; technically, the dependence on the azimuthal angle between Δ and κ is described by the conformal spin expansion. We will not go into the technicalities of the formalism but it is fair to say that for the leading helicity amplitudes, the changes from pQCD two-gluon exchange to scaling BFKL approximation are for the most part marginal. The sensitivity to the wave function of the vector meson and real photon is dramatic, though. The detailed discussion is found in the recent paper by Poludniowski *et al.* [261]; here, we summarize the major points.

The equivalent parton representation (151) makes it obvious that the helicity properties of the target dissociative reaction do not depend on the target. In their analysis of $\gamma\gamma \longrightarrow VY$ to the perturbative two-gluon exchange approximation, Ginzburg *et al.* [30] allowed for the Fermi motion of quarks parametrized in terms of vector meson distribution amplitudes with broad z-distribution and found the dominance by the spin-flip transition $\gamma_T \longrightarrow V_L$ (cf. the large-t extension of Eq. (123)). The double-flip and nonflip amplitudes have similar t-dependence and are suppressed. The found differential cross section is of the form

$$\frac{d\sigma_V(\gamma_T q \longrightarrow V_L q')}{dt} \propto \alpha_{em} m_V \Gamma(V \longrightarrow e^+ e^-) \frac{\alpha_S^4}{|t|^3}. \quad (153)$$

The flavor dependence is typical for the σ_L-dominance (cf. Eqs. (147), (174)). The sensitivity to the wave function is obvious from the much discussed unrealistic nonrelativistic limit of $z \equiv \frac{1}{2}$. Here, the helicity flip amplitude vanishes, and (see Eq. (119)) the SCHC transition dominates [262] (see also Eq. (119)); the differential cross section (153) acquires the extra factor $m_V^2/|t|$ and, furthermore, the predicted cross section exhibits an accidental, artificial, zero at $|t| = m_V^2$.

Upon the radiative corrections, the electromagnetic vertex acquires the anomalous magnetic moment (Pauli) component $\propto \sigma_{\mu\nu} p_\nu^\gamma / 2m_f$ which, as we discussed in Section 4.3.3 contributes to the chiral-odd parallel-helicity wave function of the photon. Schwinger's classic calculations show that, for virtual photons, the form factor of such a perturbative Pauli vertex vanishes $\propto m_f^2/Q^2$ (see Section 117 of the textbook [263]). Ivanov *et al.* argued [242] that, for real photons, the nonperturbative chiral-odd vertex is substantial (they relate it to the product of the quark condensate and the magnetic susceptibility of the vacuum [243]) and will enhance strongly the SCHC transition $\gamma_T \longrightarrow V_T$.

The ideas of Ivanov *et al.* [242] have been extended to the scaling BFKL approximation by Poludniowski *et al.* [261], where one can find references to early studies. The crucial point is an enhancement of the SCHC amplitude by the chiral-odd parallel-helicity component in the photon. The importance of realistic z-distributions in vector mesons is clearly seen from Fig. 21, which show the helicity amplitudes for the ρ production differential in z for chiral-even and chiral-odd photon wave function. As we stated above, for the leading chiral-even helicity amplitude $\mathcal{T}_{01}$ (M_{+0} in the notations of Poludniowski *et al.*), the changes from the pQCD two-gluon to scaling BFKL approximation are marginal. The BFKL approximation enhances further the chiral-odd contribution to the SCHC nonflip ampli-

tude and makes an approximate SCHC the dominant feature of large-t vector meson production in the studied region of $|t| \lesssim 6$ GeV^2. The double-flip amplitude is also enhanced.

Finally, making use of the scaling BFKL unintegrated glue, one is committed to the BFKL intercept (59) and prediction of the steep rise of the cross section with energy

$$\frac{d\sigma}{dt} \propto \left(\frac{W^2}{m_V^2 - t}\right)^{2\Delta_{BFKL}}, \quad (154)$$

which has been emphasized by Ginzburg *et al.* already in 1986 [30].

4.12. Beyond the Leading $\log \frac{1}{x}$ Approximation

The pQCD of the vector meson production described above is based on the manifestly leading $\log \frac{1}{x}$ BFKL formalism. Going to the NLO $\log \frac{1}{x}$ BFKL remains the major challenge to the theory. The principal feature of the leading $\log \frac{1}{x}$ approximation is that adding soft *perturbative* gluons, i.e., the higher Fock states, to the color dipole can be reabsorbed into the x-dependence of the color dipole cross section, which is equally true for DIS and vector meson production. Going to the NLO $\log \frac{1}{x}$ approximation is much more tricky. While the nearly decade long efforts have culminated in the derivation [264] of the NLO BFKL evolution kernel, the matching calculations of the effect of hard gluons in the NLO impact factors are missing. In the case of DIS, those hard gluons are of perturbative origin, but even so, despite the great progress [265, 266], the closed result for the impact factor of the virtual photon is not yet available. In the case of vector mesons, the evaluation of the NLO impact factor cannot be separated from the issue of the higher, nonperturbative, $q\bar{q}g$, Fock state of the vector meson, in which the gluon carries a finite fraction of the vector meson's momentum. With the reference to the nonrelativistic intuition, one may argue that an admixture of such a nonperturbative $q\bar{q}g$ Fock state is small in the Υ, but not the lighter quarkonia the nonrelativistic treatment of which is suspect. The issue of nonperturbative $q\bar{q}g$ and higher Fock states in light vector mesons remains open. Hence, we are bound to stay within the $q\bar{q}$ Fock state and leading $\log \frac{1}{x}$ approximations.

None of the NLO corrections is expected to change substantially the predicted x_g- and Q^2-dependences, but they affect strongly the predicted cross section. For instance, one often includes the correction for skewness
Fig. 21. The helicity amplitudes differential in $z = u$ for pQCD two-gluon and scaling BFKL approximations for $|t| = 10\ \mathrm{GeV}^2$ and $\alpha_S \Delta y \sim 2.4$, where Δy is the rapidity gap between the vector meson and debris of the proton. The pQCD two-gluon results have been multiplied by a factor of 3 (from Poludniowski *et al.* [261]).

(132) for the reason that, at small x and large $\overline{Q}^2$, it enhances the predicted cross section by a factor of 2 almost. Similarly, the real part of the dipole amplitude (126) is a NLO correction which is substantial at large $\overline{Q}^2$. A consistent treatment of the potentially more important Celmaster and Barbieri *et al.* correction (150) and its counterpart for the impact factor is not yet available. In their analysis of NLO corrections, Levin *et al.* did not consider the Celmaster and Barbieri *et al.* correction, but argued that, by analogy with the Drell–Yan production of lepton pairs, the cross section of near-threshold diffractive $c\bar{c}$ pairs acquires the K-factor [267]

$$K \approx 1 + \frac{2\pi}{3}\alpha_S, \qquad (155)$$

which, by virtue of duality arguments, shall propagate to the vector meson production cross section, while Dremin asserts that NLO Sudakov effects rather than suppresses the cross section [268]. The full-fledged NLO $\log\frac{1}{x}$ $k_\perp$-factorization analysis necessary for consistent treatment of all these corrections is not available yet.

5. HELICITY PROPERTIES OF VECTOR MESON PRODUCTION

5.1. General Introduction

The angular distribution of the exclusive production of vector mesons decaying into particle–antiparticle final state is usually described in the so-called helicity frame [42, 269]. For the unpolarized lepton beam, such as that at HERA, the cross section depends on three

angles explained in Fig. 22 for the specific case of $\rho^0 \longrightarrow \pi^+\pi^-$ production.

This angular distribution can be expressed in terms of the virtual photon density matrix $\rho_{\lambda'_\gamma \lambda_\gamma}(\Phi_h)$ (22), the helicity amplitudes of virtual photon transition with helicity λ_γ into the vector meson with helicity λ_V, $\mathcal{T}_{\lambda_V, \lambda_\gamma}$, and of the angular factors that describe the vector meson decay into the final particle–antiparticle state. For the case of decay into scalars ($\rho \longrightarrow \pi^+\pi^-$ and $\phi \longrightarrow K^+K^-$ decays), these angular factors are given by spherical harmonics Y_{1,λ_V}:

$$\frac{d\sigma}{d\cos\theta_h\, d\phi_h\, d\Phi_h} \equiv \sigma W(\cos\theta_h, \phi_h, \Phi_h)$$

$$= \sum_{\lambda_\gamma, \lambda'_\gamma;\ \lambda_V \lambda'_V} \mathcal{T}_{\lambda_V, \lambda_\gamma} \mathcal{T}^*_{\lambda'_V, \lambda'_\gamma} Y_{1,\lambda_V}(\theta_h, \phi_h) \qquad (156)$$

$$\times Y^*_{1, \lambda'_V}(\theta_h, \phi_h) \rho_{\lambda_\gamma \lambda'_\gamma}(\Phi_h).$$

In the case of the J/Ψ production, one measures the angular distribution of leptons in the decay $J/\psi \longrightarrow l^+l^-$; then, the $D^{1/2}(\theta_h, \phi_h)$-functions instead of spherical harmonics will appear in (157). Since the photon density matrix $\rho_{\lambda'_\gamma \lambda_\gamma}$ and the angular factors are known, the study of the angular dependence of the cross section reveals the helicity structure of the $\gamma^* p \longrightarrow Vp$ transition.

The conservation of the s-channel helicity in the scattering of electrons in the Coulomb field has been known since 1954 [209] (see also the textbook [210]). Motivated by the early experimental data on vector meson photo- and electroproduction, Gilman *et al.* sug-
Fig. 22. Kinematics of the process $ep \longrightarrow e\rho^0 p \longrightarrow e\pi^+\pi^- p$. The angular variables used in the determination of the helicity amplitudes from the decay distributions: Φ_h, the azimuthal angle between the (e, e') scattering plane and the (ρ^0, p') production plane; ϕ_h, the azimuthal angle between the production and decay planes; and θ_h, the polar angle of the positively-charged decay pion defined with respect to the direction of the ρ^0 momentum in the γ^*p cms system. Illustration is taken from [15].

gested the *s*-channel helicity conservation (SCHC) as the fundamental feature of diffraction scattering [269] (for the discussion of the pre-HERA experimental situation, see [42]). Within diffraction cone, the helicity of the vector meson λ_V coincides approximately with the helicity of the incident photon λ_γ (see Section 3.4.6). It is reasonable therefore to start with the case of strict *s*-channel helicity conservation (SCHC), $\lambda_V = \lambda_\gamma$.

As emphasized in Section 3.1.2, the Pomeron and all higher-lying secondary Reggeons are natural parity *t*-channel exchanges. Hereafter, we analyze the helicity properties of vector meson production assuming natural parity exchange. A good idea about why the possible contribution from unnatural parity exchange can be neglected is given by the longitudinal double-spin asymmetry.

5.2. Longitudinal Double-Spin Asymmetry and Unnatural Parity Exchange

One is familiar with the helicity structure function of the proton, $g_1(x, Q^2)$, which measures the mean helicity of partons in the longitudinally polarized proton. It is determined experimentally in the DIS of the longitudinally polarized leptons off longitudinally polarized proton target, where the polarized leptons serve as the source of circularly polarized photons. The measured cross section is proportional to the imaginary part of the helicity conserving forward Compton scattering amplitude,

$$
\mathscr{T}_{\lambda_\gamma\lambda_N, \lambda_\gamma\lambda_N} \propto F_1(x, Q^2)
$$
$$
+ \lambda_\gamma\lambda_N g_1(x, Q^2) \propto 1 + A_{LL}^{(\text{DIS})}\lambda_\gamma\lambda_N, \tag{157}
$$

where λ_γ and λ_N are the helicities of the photon and target nucleon ($\lambda_N = \pm 1$). Such a helicity dependence for transverse photons emerges naturally for the axial-vector (A_1, …) meson exchange. The term $\propto g_1(x, Q^2)$ changes the sign when the circular polarization of the photon is flipped and, from the *t*-channel exchange point of view, corresponds to the unnatural parity exchange (see Eq. (88)). As explained in Section 1.3, the vector meson production amplitude derives from the Compton amplitude by analytic continuation in the virtuality of the photon to the vector meson pole, which should not change dramatically the asymmetry parameter in the amplitude. Consequently, if one parametrizes the unnatural parity exchange into the transverse vector meson production amplitude as

$$
\mathscr{T}_{\lambda_V\lambda_N, \lambda_\gamma\lambda_N}\big|_{\lambda_V = \lambda_\gamma} \propto 1 + \frac{1}{2}A_{LL}^V \lambda_\gamma\lambda_N, \tag{158}
$$

then the natural expectation for the transverse cross section will be σ_T is [270]

$$
A_{LL}^V \approx 2A_{LL}^{(\text{DIS})}. \tag{159}
$$

There is a purposeful difference between expansions (157) and (158) because, in the vector meson production, one measures the differential cross section $\propto |\mathscr{T}|^2$. In σ_L–σ_T unseparated vector meson production, the asymmetry is diluted for the presence of σ_L,

$$A_1^V \approx \frac{A_{LL}^V}{1 + R_V} \approx \frac{2A_1}{1 + R_V} \qquad (160)$$

(here, we are back to the usual notation $A_1 = A_{LL}^{(DIS)}$), hence, the dilution factor $(1 + R_V)$ in (160) compared to (159). As a matter of fact, such a relationship between the longitudinal double-spin asymmetries for DIS and vector meson production has already been suggested in 1976 by Fraas on the basis of the vector dominance model [271].

The results of the first experimental determination of A_1^ρ for the diffractive ρ production in the HERMES experiment [272] are shown in Fig. 23 in comparison with the estimates from the DIS data based on Eq. (160) but without the dilution of A_1^V by the factor $(1 + R_V)$. A summary of the high-precision experimental data on the ratio of polarized, helicity, $g_1(x, Q^2)$, to unpolarized, $F_1(x, Q^2)$, proton structure function is shown in Fig. 23; the important point is that the effects of unnatural parity exchange vanish at small x (for pQCD arguments in favor of that, see [273–275]).

5.3. The Angular Distribution in the SCHC Approximation

5.3.1. Theoretical expectation: angular distributions. Within SCHC and natural parity exchange, we are left with two independent helicity amplitudes, $\mathcal{T}_{11}$ and $\mathcal{T}_{00}$. Then, the angular dependence of reaction $\gamma^* p \longrightarrow Vp$, with V decaying into two scalars, is

$$W(\cos\theta_h, \phi_h, \Phi_h)$$

$$= \frac{1}{N}\frac{3}{4\pi}\left[\epsilon|\mathcal{T}_{00}|^2\cos^2\theta_h + \frac{1}{2}|\mathcal{T}_{11}|^2\sin^2\theta_h\right.$$

$$\left. + \frac{1}{2}\epsilon|\mathcal{T}_{11}|^2\sin^2\theta_h\cos2(\Phi_h - \phi_h)\right. \qquad (161)$$

$$\left. - \sqrt{2\epsilon(1+\epsilon)}\operatorname{Re}(\mathcal{T}_{11}\mathcal{T}_{00}^*)\sin\theta_h\cos\theta_h\cos(\Phi_h - \phi_h)\right],$$

where $N = |\mathcal{T}_{11}|^2 + \epsilon|\mathcal{T}_{00}|^2$, and ϵ is defined in (22). The first line in (161) is the contribution of diagonal terms of the photon density matrix, i.e., with $\lambda_\gamma = \lambda_\gamma'$; the second line is the interference of transverse photons with opposite helicities, $\lambda_\gamma = -\lambda_\gamma' = \pm 1$; the last line is the interference between the transverse and longitudinal photons. Note that angular dependence (161) involves only a single azimuthal angle $\psi = \Phi_h - \phi_h$ between the (e, e') and decay planes.

One can reparametrize, and analyze, the angular distribution (161) in terms r_{ij}^α, which compose the spin-density matrix of a vector meson [67]. The generic case

and the involved notations for the r_{ij}^α are explained in Section 5.3.1; here, we only notice that under the assumption of SCHC many the elements of r_{ij}^α do vanish, and (161) takes the form

$$W(\cos\theta_h, \phi_h, \Phi_h)$$

$$= \frac{3}{4\pi}\left[\frac{1}{2}(1 - r_{00}^{04}) + \frac{1}{2}(3r_{00}^{04} - 1)\cos^2\theta_h\right.$$

$$+ \epsilon\cos2\Phi_h\sqrt{2}\sin^2\theta_h\cos2\phi_h r_{1-1}^1$$

$$- \epsilon\sin2\Phi_h\sin^2\theta_h\sin2\phi_h\operatorname{Im}\{r_{1-1}^2\} \qquad (162)$$

$$- \sqrt{2\epsilon(1+\epsilon)}\cos\Phi_h\sin2\theta_h\cos\phi_h\sqrt{2}\operatorname{Re}\{r_{10}^5\}$$

$$+ \left.\sqrt{2\epsilon(1+\epsilon)}\sin\Phi_h\sin2\theta_h\sin2\phi_h\sqrt{2}\operatorname{Im}\{r_{10}^6\}\right].$$

It contains five nonzero spin-density matrix elements among which only three are independent due to the relations (88). Their expression via the helicity amplitudes reads

$$r_{00}^{04} = \frac{\epsilon|\mathcal{T}_{00}|^2}{|\mathcal{T}_{11}|^2 + \epsilon|\mathcal{T}_{00}|^2},$$

$$r_{1-1}^1 = -\operatorname{Im}\{r_{1-1}^2\} = \frac{1}{2}\frac{|\mathcal{T}_{11}|^2}{|\mathcal{T}_{11}|^2 + \epsilon|\mathcal{T}_{00}|^2}, \qquad (163)$$

$$\operatorname{Re}\{r_{10}^5\} = -\operatorname{Im}\{r_{10}^6\} = \frac{1}{2\sqrt{2}}\frac{\operatorname{Re}\{\mathcal{T}_{11}\mathcal{T}_{00}^*\}}{|\mathcal{T}_{11}|^2 + \epsilon|\mathcal{T}_{00}|^2}.$$

Under the SCHC conservation, the ratio of the longitudinal to transverse cross sections (26) is expressed only via matrix element r_{00}^{04},

$$R_V = \frac{1}{\epsilon}\frac{r_{00}^{04}}{1 - r_{00}^{04}}, \qquad (164)$$

while the relative phase δ between the $\mathcal{T}_{11}$ and $\mathcal{T}_{00}$ amplitudes can be determined via

$$\cos\delta = \frac{1 + \epsilon R_V}{\sqrt{R_V/2}}(\operatorname{Re}\{r_{10}^5\} - \operatorname{Im}\{r_{10}^6\}). \qquad (165)$$

5.3.2. Experimental results. Figure 24 shows the results of ZEUS and H1 on the five "nonzero-SCHC" (hereafter, just "SCHC") matrix elements mentioned above. These matrix elements are placed in three rows. The first line corresponds to diagonal terms; the second line is the interference of transverse photons with opposite helicities; the last line is the interference between transverse and longitudinal photons.

The matrix element r_{00}^{04} is extracted from the single-differential cross section $d\sigma/d\cos\theta_h$. The photoproduc-
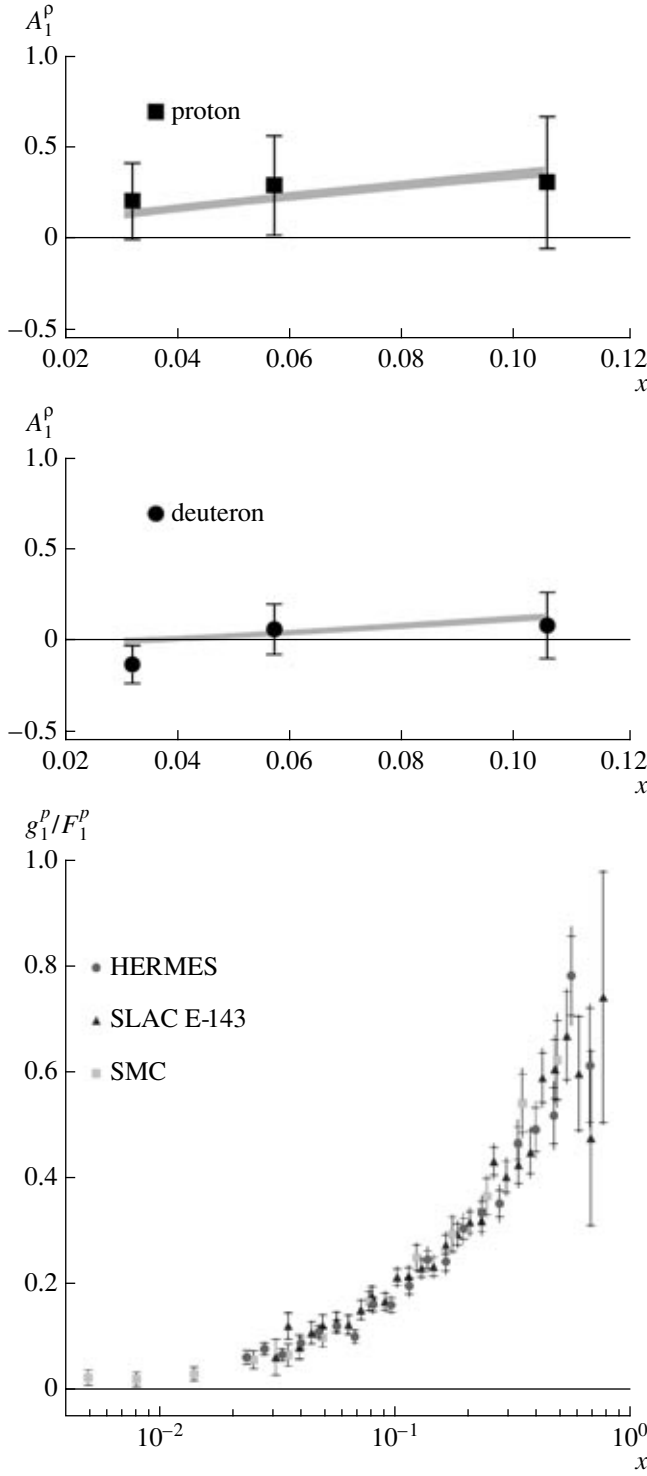

Fig. 23. Upper two plots show the x-dependence of the longitudinal double-spin asymmetry A_1^ρ in exclusive ρ^0 meson electroproduction on the proton (top) and deuteron (bottom). The data from HERMES [272] are compared to the expectations from Eq. (160) based on the DIS data from the bottom plot, which shows the ratio of polarized to unpolarized proton structure function from the SMC, E143, and HERMES experiments (for the review and references, see [276]).

tion measurements [68, 71, 277, 278] confirm that, at $Q^2 = 0$, the matrix element r_{00}^{04} is zero within experimental uncertainties for ρ, ϕ, and J/ψ mesons. This should be expected, since in the limit $Q^2 \longrightarrow 0$, the longitudinal cross section must vanish. The behavior of r_{00}^{04} as a function of Q^2, W, and t for ρ mesons is shown in Figs. 24 and 25.

The steep Q^2 dependence of r_{00}^{04} is mainly due to the gauge invariance driven factor $\sim Q^2/m_V^2$ present in the longitudinal cross section (see (81), (82)). The pattern of the Q^2 dependence is very similar for all the light vector mesons and differs in the case of the J/ψ (not shown). The matrix element r_{00}^{04} is the main source of the determination of the ratio $R_V = \sigma_L/\sigma_T$, whose Q^2-behavior will be discussed in detail in the forthcoming Section, 6.3. The t and W dependences of r_{00}^{04} are consistent with being flat. This indicates that the energy dependence of the longitudinal, $\mathcal{T}_{00}$, and transverse, $\mathcal{T}_{11}$, amplitudes is very close to each other, in agreement with theoretical expectations. The same holds also for the t-dependence of the longitudinal and transverse amplitudes.

The Q^2-behavior of the other SCHC matrix elements can be read off from Eq. (163). The elements r_{1-1}^1 and Im$\{r_{1-1}^2\}$ should approach $\pm 1/2$, respectively, in the photoproduction limit and are expected to decrease with Q^2 increase approximately as $1/(2R)$. This tendency is well observed in the data. The longitudinal–transverse (LT) interference driven elements Re$\{r_{10}^5\}$ and Im$\{r_{10}^6\}$ should be $\propto Q$ at small Q^2 and fall off with Q^2 growth as $1/Q$. The experimental data from the ZEUS Collaboration do follow this expectation; the experimental data from H1 on $r_{10}^{5,6}$ exhibit a certain departure from the theoretical expectation.

As we discussed in Section 4.8.1, because of the slightly different hard scales $\overline{Q}_L^2$ and $\overline{Q}_T^2$, the two helicity amplitudes $\mathcal{T}_{11}$ and $\mathcal{T}_{00}$ can have a slightly different energy dependence (see Sections 3.3.1–3.3.3 and the discussion of the experimental data in Section 7). Then, the derivative analyticity (126) would predict the non-vanishing, but very small, in the range of 1°–3°, relative phase δ of the two amplitudes. The results of the H1 determination [16] of $\cos\delta$ from Eq. (165) are shown in Fig. 26. The combined value of $\cos\delta$ suggests the statistically significant departure from 1,

$$\cos\delta = 0.925 \pm 0.022_{-0.022}^{+0.011}; \qquad (166)$$

the sizeable relative phase $\delta \sim 10°$–$20°$ is difficult to accommodate in theory. The error bars are large,

The first matrix element corresponds to the diagonal terms in photon density matrix; the second line is the interference of transverse photons with opposite helicities; the last line is the interference between transverse and longitudinal photons. The lines show the k_t-factorization predictions [54, 55].

though, it must be noted that ZEUS assumes $\delta = 0$ and still obtains good fits to the angular distribution.

5.4. Angular Dependence beyond SCHC

5.4.1. Theoretical expectations. Without the assumption of s-channel helicity conservation, and supposing the natural parity exchange (see Section 5.2.3), one is left with five independent helicity amplitudes. The angular dependence of the cross section (for spinless particle–antiparticle final state such as in the decay $\rho \longrightarrow \pi^+\pi^-$, $\phi \longrightarrow K^+K^-$) is parametrized in terms of 15 spin density matrix elements [67]:

$$\frac{1}{\sigma}\frac{d\sigma}{d\cos\theta_h d\phi_h d\Phi_h} \equiv W(\cos\theta_h, \phi_h, \Phi_h)$$

$$-\sqrt{2}\mathrm{Re}\{r_{10}^5\}\sin 2\theta_h\cos\phi_h - r_{1-1}^5\sin^2\theta_h\cos 2\phi_h)$$

$$+\sqrt{2\epsilon(1+\epsilon)}\sin\Phi_h(\sqrt{2}\mathrm{Im}\{r_{10}^6\}\sin 2\theta_h\sin\phi_h$$

$$+\mathrm{Im}\{r_{1-1}^6\}\sin^2\theta_h\sin 2\phi_h)\Big].$$

One can develop an intuition when reading this expression. The subscripts i, $k = -1$, 0, 1 of the matrix elements r_{ik}^α indicate the vector meson helicities λ_V and λ_V' of the amplitudes interfering. Dependence on Φ_h shows the helicities of the photon of the interfering amplitudes. As before, the Φ_h-independent terms are diagonal in photon helicities; they are accompanied by superscript 04. Terms $\propto\cos 2\Phi_h$ and $\propto\sin 2\Phi_h$ originate from the interference of the transverse photons with opposite helicities; these are accompanied by super-

scripts 1 and 2. Terms $\propto\cos\Phi_h$ and $\propto\sin\Phi_h$ appear from the interference of the transverse and longitudinal photons; these are accompanied by superscripts 5 and 6. The nature of each r_{ik}^α can then be understood from its indices. For example, r_{11}^1 comes from the interference of photons of helicities $+1$ and -1 and from vector mesons with both helicities equal to 1 or -1. Therefore, r_{11}^1 must be proportional to the double spin-flip amplitude.

The correspondence between the matrix elements r_{ik}^α, the helicity amplitudes, and their SCHC and SCHNC properties is as follows:

SCHC:

$$r_{00}^{04} = \epsilon|\mathcal{T}_{00}|^2 + |\mathcal{T}_{01}|^2,$$

$$r_{1-1}^1 = \frac{1}{2}|\mathcal{T}_{11}|^2 + \frac{1}{2}|\mathcal{T}_{1-1}|^2,$$

$$\mathrm{Im}\{r_{1-1}^2\} = -\frac{1}{2}|\mathcal{T}_{11}|^2 + \frac{1}{2}|\mathcal{T}_{1-1}|^2,$$

$$(168)$$

$$\mathrm{Re}\{r_{10}^5\} = \frac{1}{2\sqrt{2}}\mathrm{Re}\{\mathcal{T}_{11}\mathcal{T}_{00}^*\} + \frac{1}{\sqrt{2}}\mathrm{Re}\{\mathcal{T}_{10}\mathcal{T}_{01}^*\}$$

$$-\frac{1}{2\sqrt{2}}\mathrm{Re}\{\mathcal{T}_{1-1}\mathcal{T}_{00}^*\},$$

$$\mathrm{Im}\{r_{10}^6\} = -\frac{1}{2\sqrt{2}}\mathrm{Re}\{\mathcal{T}_{11}\mathcal{T}_{00}^*\} - \frac{1}{2\sqrt{2}}\mathrm{Re}\{\mathcal{T}_{1-1}\mathcal{T}_{00}^*\};$$

strong SCHNC from single-flip $\gamma_T \longrightarrow V_L$, $\propto\mathcal{T}_{01}$:

$$\mathrm{Re}\{r_{10}^{04}\} = \frac{1}{2}\mathrm{Re}\{\mathcal{T}_{11}\mathcal{T}_{01}^*\} + \epsilon\,\mathrm{Re}\{\mathcal{T}_{10}\mathcal{T}_{00}^*\}$$

$$+\frac{1}{2}\mathrm{Re}\{\mathcal{T}_{1-1}\mathcal{T}_{0-1}^*\},$$

$$(169)$$

$$\mathrm{Re}\{r_{10}^1\} = \frac{1}{2}\mathrm{Re}\{\mathcal{T}_{11}\mathcal{T}_{0-1}^*\} + \frac{1}{2}\mathrm{Re}\{\mathcal{T}_{1-1}\mathcal{T}_{01}^*\},$$

$$\mathrm{Im}\{r_{10}^2\} = -\frac{1}{2}\mathrm{Re}\{\mathcal{T}_{11}\mathcal{T}_{0-1}^*\} + \frac{1}{2}\mathrm{Re}\{\mathcal{T}_{1-1}\mathcal{T}_{01}^*\},$$

$$r_{00}^5 = \sqrt{2}\mathrm{Re}\{\mathcal{T}_{11}\mathcal{T}_{01}^*\};$$

weak SCHNC from single-flip $\gamma_L \longrightarrow V_T$, $\propto\mathcal{T}_{10}$:

$$r_{11}^5 = \frac{1}{\sqrt{2}}\mathrm{Re}\{\mathcal{T}_{10}\mathcal{T}_{11}^*\} - \frac{1}{\sqrt{2}}\mathrm{Re}\{\mathcal{T}_{10}\mathcal{T}_{1-1}^*\},$$

$$r_{1-1}^5 = \frac{1}{\sqrt{2}}\mathrm{Re}\{\mathcal{T}_{11}\mathcal{T}_{-10}^*\} + \frac{1}{\sqrt{2}}\mathrm{Re}\{\mathcal{T}_{10}\mathcal{T}_{-11}^*\}, \quad (170)$$

$$\mathrm{Im}\{r_{1-1}^6\} = -\frac{1}{\sqrt{2}}\mathrm{Re}\{\mathcal{T}_{-10}\mathcal{T}_{11}^*\} + \frac{1}{\sqrt{2}}\mathrm{Re}\{\mathcal{T}_{10}\mathcal{T}_{-11}^*\};$$

double SCHNC from the double-flip or two single-flips:

$$r_{1-1}^{04} = -\epsilon|\mathcal{T}_{10}|^2 + \mathrm{Re}\{\mathcal{T}_{11}\mathcal{T}_{1-1}^*\},$$

$$r_{11}^1 = \mathrm{Re}\{\mathcal{T}_{1-1}\mathcal{T}_{11}^*\}, \qquad (171)$$

$$r_{00}^1 = -|\mathcal{T}_{01}|^2.$$

It is understood that the right-hand side of each and every line must be also divided by $\epsilon(|\mathcal{T}_{00}|^2 + 2|\mathcal{T}_{10}|^2) + |\mathcal{T}_{11}|^2 + |\mathcal{T}_{1-1}|^2 + |\mathcal{T}_{01}|^2$.

The classification of each set of density matrix elements (168)–(171) in the left column of this table can be understood as follows: at large Q^2, the largest SCHNC amplitude is $\mathcal{T}_{01}$ (the transverse photon to longitudinal vector meson transition). Therefore, the stronger SCHC violation is expected in density matrix elements of the second group, in particular, in r_{00}^5. At small Q^2, the double-flip $\mathcal{T}_{1-1}$ is predicted to be the largest SCHNC amplitude as it is soft-dominated and does not require the longitudinal Fermi motion. Therefore, at small Q^2, the largest non-SCHC spin density matrix elements is expected to be r_{1-1}^{04} and r_{00}^1. The amplitude $\mathcal{T}_{10}$ vanishes in the photoproduction limit, is of higher twist at large Q^2, and is expected to be always small.

As discussed in Section 3.4.6, the small-t behavior of various amplitudes is governed solely by the value of the helicity flip: the matrix elements from the second (Eq. (169)) and third (Eq. (170)) groups are expected to be $\propto \sqrt{|t'|}$; the elements in the last group (Eq. (170)) are $\propto|t'|$.

5.4.2. Experimental results: helicity properties at small t. In the experiment, the density matrix elements are obtained by minimizing the difference between the three-dimensional ($\cos\theta_h$, ϕ_h, Φ_h) angular distributions of the data and those of the simulated events. Figure 27 shows combined ZEUS [15] and H1 [16] results of this procedure for the ρ meson production. Results for ϕ mesons are presented in Fig. 28.

All the matrix elements are placed in six rows. The first three rows are the same as in Fig. 24 and show the spin density matrix elements coming from SCHC transitions. The last three rows represent the SCHNC matrix elements, which would vanish in the case of strict SCHC, for the definitions and classification of SCHNC as strong, weak, and double (see Eqs. (168)–(171) and discussion in Section 5.3.1). The fourth row shows the four matrix amplitudes proportional to the single-flip helicity amplitude $\mathcal{T}_{01}$; the fifth row shows the matrix elements that are proportional to the single-flip helicity amplitude $\mathcal{T}_{10}$; the last row shows matrix elements with two helicity flips, either as a double-flip amplitude or as a product (square) of two single-flip amplitudes.

Among the SCHNC spin density matrix elements, the best measured ones are the combinations $2r_{11}^1 + r_{00}^1$

and $2r_{11}^5 + r_{00}^5$, which describe the single-differential cross section in angle Φ_h after the integration over $\cos\theta_h$:

$$\frac{d\sigma}{d\Phi_h} \propto 1 + \sqrt{2\epsilon(1+\epsilon)}\cos\Phi_h(r_{00}^5 + 2r_{11}^5)$$
$$- \epsilon\cos2\Phi_h(r_{00}^1 + 2r_{11}^1). \qquad (172)$$

Figure 29 also shows the recent H1 measurement of the Q^2-dependence of these matrix elements for the case of ρ mesons [85]. The first combination is significantly nonzero, while the second is compatible with zero. The results of the direct fit to the entire angular distribution shown in Fig. 27 indicate that it is the large nonzero value of r_{00}^5 that is a source of departure from the SCHC in the first combination. Since this matrix element is proportional to the $\mathrm{Re}(\mathcal{T}_{00}\mathcal{T}_{01}^*)$, it indicates that the single-flip amplitude $\mathcal{T}_{01}$ is not zero. The data shown in Fig. 29 give an estimate of the relative strength of this amplitude at an average value of $|t| \approx 0.15$ GeV^2:

$$\frac{|\mathcal{T}_{01}|}{\sqrt{|\mathcal{T}_{11}|^2 + |\mathcal{T}_{00}|^2}} \approx r_{00}^5\sqrt{\frac{1+R}{2R}} \approx 8 \pm 3\%. \qquad (173)$$

The dominance of r_{00}^5 among the helicity violating amplitudes at large Q^2 is in agreement with theoretical expectations [54, 170, 212]. All the other matrix elements do not differ significantly from zero. There is, however, some indication that the double-flip amplitude is nonzero at small Q^2 (see the last row in Fig. 27).

The t-dependence of the s-channel helicity violating amplitudes has already been shown in Fig. 29 within the diffraction cone. In Fig. 30, the data [82] on helicity violating matrix elements $2r_{11}^1 + r_{00}^1$ and $2r_{11}^5 + r_{00}^5$ within extended t-region, $|t'| < 2$ GeV^2, are shown. The behavior of both of these combinations is compatible with $\propto \sqrt{|t'|}$ and confirms theoretical expectations. For comparison, in the same figure, we show the t-behavior of the helicity conserving matrix element r_{00}^{04} within the same region, which is compatible with the constant.

5.4.3. Experimental results: helicity properties at large t. At large t, only the proton dissociative reaction $\gamma p \longrightarrow VY$ has been studied. The experimental data on the spin-density matrix elements from the recent ZEUS measurement [77] of the large-t ρ, ϕ, and J/ψ photoproduction are shown in Figs. 31, 32, and 34 in combination with the lower-t data [76]; the H1 results [79] are shown in Fig. 33.

The dominant feature of the DIS data within the diffraction cone, $|t| \lesssim 1$ GeV^2, was large r_{00}^{04} driven by the dominant σ_L from the transition $\gamma_L \longrightarrow V_L$. Such a tran-
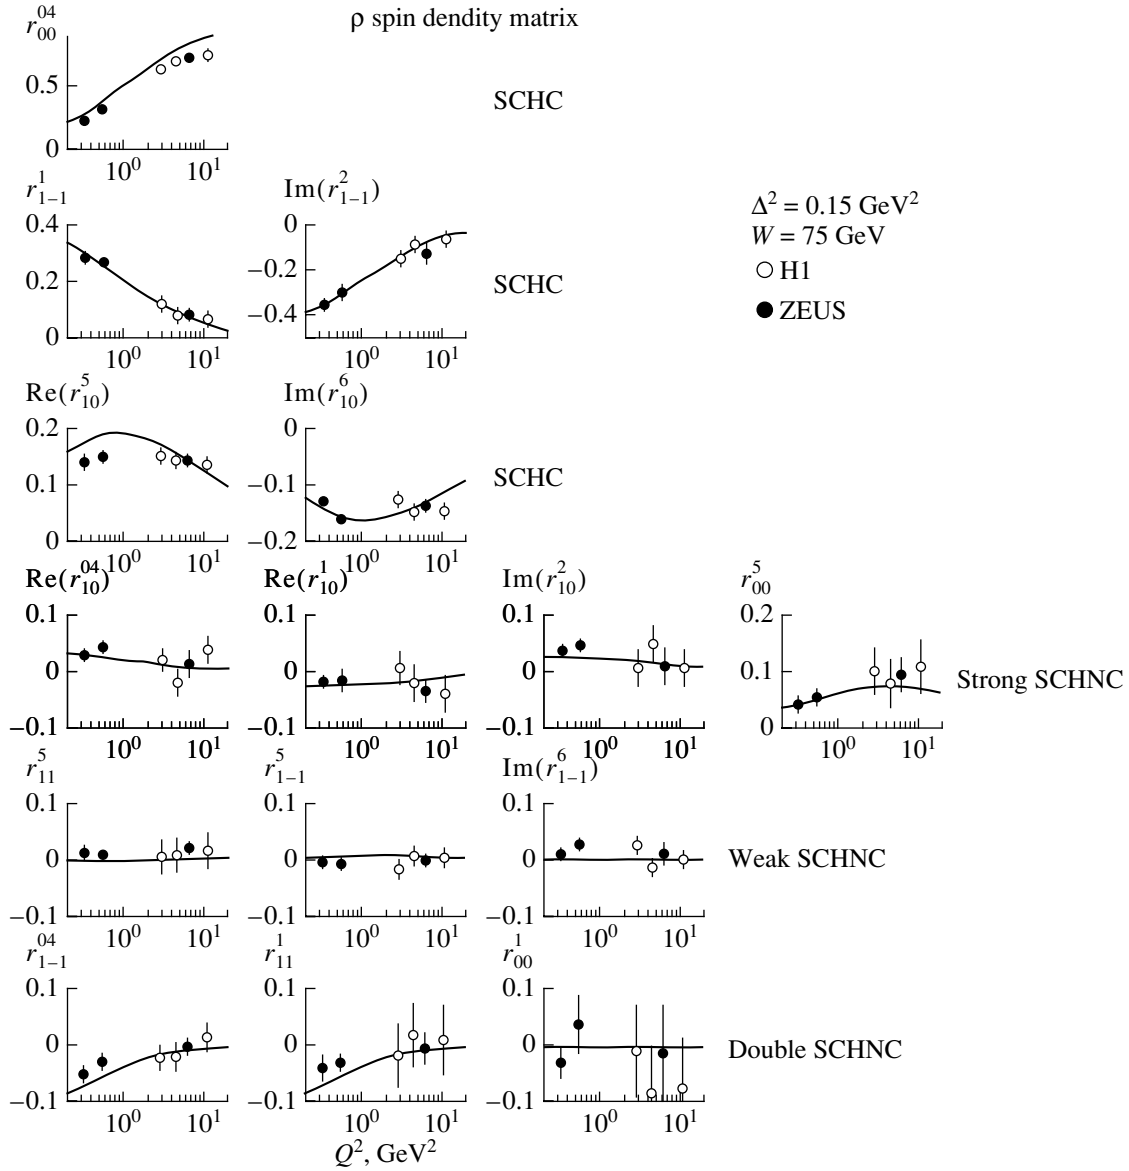

IVANOV *et al.*

Fig. 27. The spin-density matrix elements measured in the reaction $\gamma^* p \longrightarrow \rho p$ as a function of Q^2. The first three rows are the same as in Fig. 24 and show the SCHC matrix elements. The solid symbols present the ZEUS [15] and the open circles the H1 [16] results. The curves represent the k_t-factorization calculations [54, 55].

sition is absent in real photoproduction. Figures 31 and 32 show that the matrix element r_{10}^{04} is positive-valued, and definitely a nonvanishing one. The results for r_{00}^{04} show that the probability to produce longitudinal ρ or ϕ mesons from a transverse photon increases with $|t|$ up to 4–9% but is nowhere close to the SCHNC dominance of σ_L expected in the pQCD two-gluon model of Ginzburg *et al.* [30] with the chiral-even photon–quark–antiquark vertex. The matrix element r_{1-1}^{04} is numerically substantial and gives solid evidence for a double-flip contribution. All the spin density matrix elements shown in Figs. 31 and 32 are small, so that the SCHC is the empirical feature of large-t production.

Within the theoretical approaches reviewed in Section 4.10, the sole source of approximate SCHC is the chiral-odd photon–quark–antiquark vertex. The theoretical calculations [261] are shown in Figs. 33 and 34. The pQCD two-gluon approximation grossly overpredicts r_{00}^{04} for all vector mesons. The BFKL model correctly reproduces the gross features of r_{00}^{04} and r_{1-1}^{04} but predicts the wrong sign of r_{10}^{04}. The shown theoretical results are for the so-called asymptotic vector meson distribution amplitude, but the sensitivity to the model wave function is weak and cannot explain this sign conflict with the experiment.
Fig. 28. The spin-density matrix elements measured in the reaction $\gamma^* p \longrightarrow \phi p$ as a function of Q^2. The notation is the same as in Fig. 27. The curves represent the k_t-factorization calculations [54, 55].

For the heavy quarks in the J/Ψ, the Fermi motion is slow and the BFKL calculations predict much smaller helicity flip effects compared to the results for the light vector mesons (cf. Figs. 33 and 34).

6. THE Q^2 DEPENDENCE

6.1. Total Cross Section $\gamma^* p \longrightarrow V p$

6.1.1. Theoretical expectations: what is the correct hard scale for the Q^2 dependence? As emphasized in the introduction (see Section 1.3), the vector meson production at a given Q^2 probes the gluon content of a target at pQCD factorization scale $\overline{Q}^2 \sim (Q^2 + m_V^2)/4$ (see (9)). Theoretical predictions of the Q^2-dependence of the vector meson production cross section in the color dipole approach were described in detail in Sections 3.4.2 and 4.9. Besides, Section 4.8 shows how the leading $\log Q^2$ approximation results are recovered, and improved upon, in the more consistent $k_\perp$-factorization approach at large Q^2.

The theoretical expectation for the shape of the Q^2-dependence of the transverse amplitude can be read off Eqs. (78), (79), and (147). Performing the t-integration
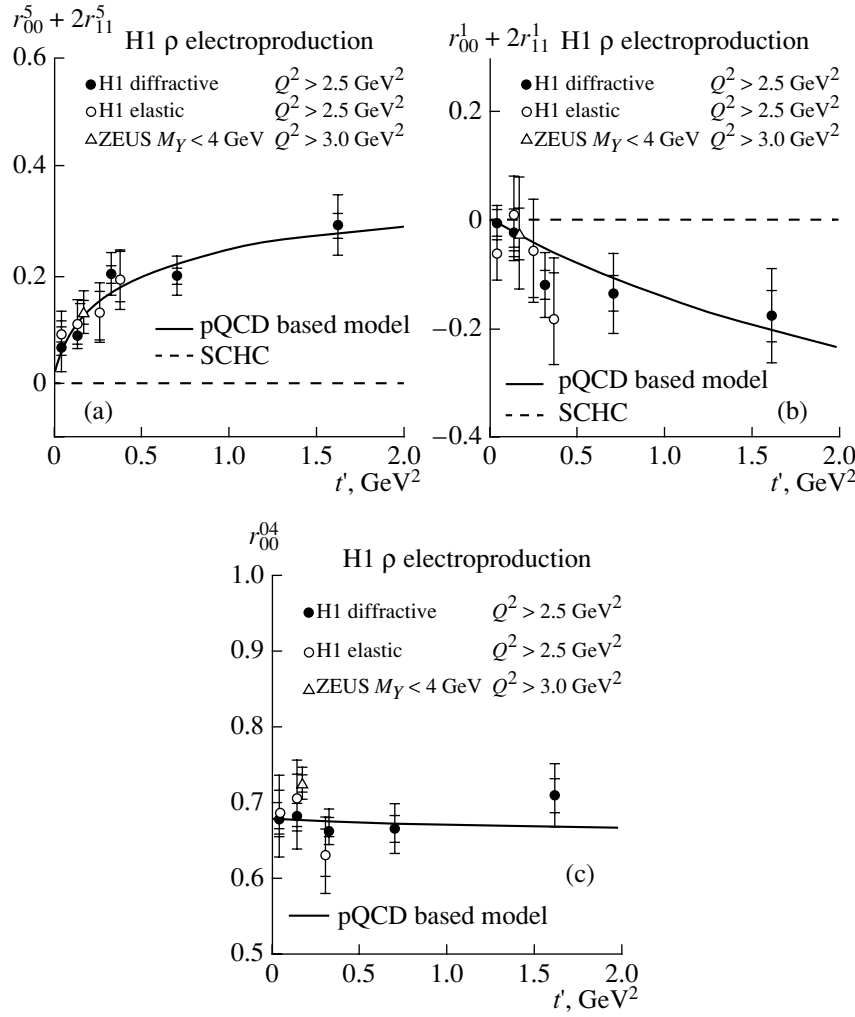

H1 ρ electroproduction

Fig. 29. The H1 and ZEUS measurement ([85] and references therein) of the combinations of SCHNC spin density matrix elements $r_{00}^5 + 2r_{11}^5$ and $r_{00}^1 + 2r_{11}^1$ as a function of Q^2, W, and t.

in (147) and combining σ_T and σ_L, one finds the nonrelativistic master formula

$$\sigma_V = \sigma_T + \sigma_L \approx \frac{\pi^3 m_V \Gamma(V \longrightarrow e^+e^-)}{12\alpha_{em}b_V(\overline{Q}^2)\overline{Q}^8} \tag{174}$$
$$\times \left(Q^2 + \frac{m_V^2}{R_{LT}}\right)[\alpha_s(\overline{Q}^2)G(x_g, \overline{Q}_{GL}^2)]^2.$$

Although absolute normalization, the exact value of the pQCD scale $\overline{Q}^2$ and the departure of R_{LT} from the nonrelativistic quark model expectation $R_{LT} = 1$ do depend on the wave function of the vector meson, and the contribution from the helicity-flip transitions, has not been included; Eq. (174) contains all the ingredients of the full pQCD description.

One can present σ_V either as $\sigma_V = \sigma_T(1 + R_V)$ and use the theoretical approximations for σ_T or substitute $\sigma_T = \sigma_L/R_V$ and test the theoretical predictions for σ_L. Brodsky *et al.* [23] argued that the endpoint, $z \sim 0$, $z \sim 1$ contributions are minimal in, and the pQCD evaluations are more reliable for the σ_L, and our representation (174) corresponds to the latter, preferred, choice.

The longitudinal cross section is small at $Q^2 \lesssim m_V^2$ but becomes the dominant feature at larger Q^2 and tames further the decrease of the total cross section at large Q^2. In view of $R_{LT} \sim 1$ at small Q^2, and because the M_V^2 term can be neglected at large Q^2, the factor $\left(Q^2 + \frac{m_V^2}{R_{LT}}\right)$ in the master formula is not very different from $(Q^2 + m_V^2)$. Then, the Q^2-behavior of the total cross section would have been $\sim(\overline{Q}^2)^{-n_V}$ with the exponent $n_V = 3$ modulated by the gluon density squared. As we will see below, $R_{LT} < 1$ and steadily decreases with Q^2, so that, even without the scaling violations the expected exponent $n_V < 3$.

Finally, the Q^2 dependence of the diffraction slope cannot be ignored. As we argued in Section 3.4.2, the diffraction slope $b_V(\overline{Q}^2)$ decreases with growing $(Q^2 + m_V^2)$, which also enhances slightly σ_V at large Q^2. As a matter of fact, the diffraction slope too is a function of $\overline{Q}^2$ rather than Q^2.

To summarize, there are strong theoretical reasons [49, 279] for the presentation of the experimental data as a function of either the scanning radius r_S or $(Q^2 + m_V^2)$. In such a presentation, the major flavor dependence is in the explicit factor $m_V\Gamma(V \longrightarrow e^+e^-)$. There is also a hidden dependence of the absolute normalization, R_{LT} and of the exact dependence of the hard scale $\overline{Q}^2$ on $(Q^2 + m_V^2)$,

Fig. 30. The H1 and ZEUS measurement ([82] and references therein) of the t'-dependence of combinations of SCHNC spin density matrix elements $r_{00}^1 + 2r_{11}^1$ and $r_{00}^5 + 2r_{11}^5$ compared with that of the behavior of the SCHC matrix element r_{00}^{04}. The solid curves are from pQCD calculations by Ivanov and Kirschner [212].

all of which depend on the wave function of vector mesons [21, 38].

6.1.2. Theoretical expectations: the impact of x_g-dependent scaling violations on the Q^2 dependence. The predicted Q^2-dependence is driven mainly by two phenomena: the shrinkage of the photon light-cone wave function with Q^2 and the resulting decrease of the scanning radius, and the nontrivial Q^2-dependence of the gluon density at fixed W. The former property leads to the strong decrease of the transverse cross section $\sim(\overline{Q}^2)^{-4}$ at a sufficiently large $\overline{Q}^2$. The gluon density, $G(x_g, \overline{Q}_G^2)$, at a fixed W, depends on $\overline{Q}^2$ also via $x_g \approx \overline{Q}^2/W^2$. At small to moderately large Q^2, one observes the quick rise of the small-x_g gluon density because of the scaling violations. At larger Q^2, the values of x_g are larger, the scaling violations are weaker, and the

decrease of the gluon density towards large x_g takes over (see Fig. 20). Because of such a convex Q^2 dependence of $G(x_g, \overline{Q}_G^2)$ in the $\log\sigma_V - \log\overline{Q}^2$ plot, one must see the convex curve.

6.1.3. The Q^2-dependence: The experimental data. The change of the character of the Q^2-dependence from small to large Q^2 is best seen in the data for light vector mesons. The experimental data on the Q^2-dependence of the ρ^0 production are shown in Fig. 35. The upper plot in Fig. 35 shows the ZEUS data. The low-Q^2 data, $Q^2 < 1$ GeV^2, are dominated by $\sigma_T(Q^2)$ and were fitted to the form

$$\sigma_\rho(Q^2) \propto \frac{1 + R_\rho(Q^2)}{(Q^2 + m_{\text{eff}}^2)^{n_\rho}}, \tag{175}$$
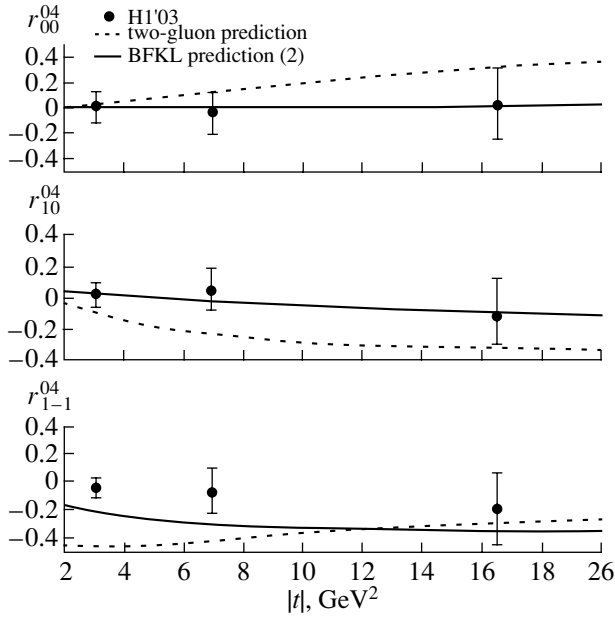

Fig. 32. The spin density matrix elements for proton-disso-ciative J/ψ production as a function of $-t$ measured by ZEUS [77]. The SCHC prediction is shown as the dashed curve.

Fig. 31. The spin density matrix elements for proton-dissociative ρ production (top panel) and ϕ production (bottom panel) as a function of $-t$ measured by ZEUS [77] (black symbols) and [76] (open symbols). The SCHC prediction is shown as the dashed curve.

where $R_\rho(Q^2) = \sigma_L/\sigma_T$ and the exponent $n_\rho \equiv 2$ as dictated by VDM. The dotted curve shows the result of the fit including the real photoproduction point. The fit

yields $m_{\mathrm{eff}} = 0.66 \pm 0.11$ GeV, which is close to the mass of the ρ-meson as expected in VDM.

The VDM value of the exponent $n_\rho = 2$ for the low-Q^2 data must be compared to the large-Q^2 pQCD expectation, $n = 4$, without scaling violations (see Eq. (81)). Indeed, at higher Q^2, the cross section of ρ production steadily departs from the dotted curve. The parametrization of the form

$$\sigma_V(Q^2) \propto \frac{1}{\left(Q^2 + m_V^2\right)^{n_V}} \qquad (176)$$

yielded $n_\rho = 2.32 \pm 0.10$ for ZEUS 95 data [81] at $Q^2 > 5$ GeV^2, $n_\rho = 2.24 \pm 0.09$ for H1 96 data [16], and $n_\rho = 2.60 \pm 0.04$ for preliminary H1 data at $Q^2 > 8$ GeV^2 [85]. The effective exponent n_ρ of the Q^2-decrease rises steadily with the region being fitted, from 2 in the soft region to 2.6 at the highest Q^2, in good agreement with the theoretical expectations of the convex $\sigma_V(Q^2)$.

Now, we comment on the comparison with theoretical predictions from the $k_\perp$-factorization [54, 55]. As we cautioned in Section 1.4, the onset of the truly pQCD hard regime for the light ρ-mesons requires large Q^2 (see Eq. (13)). At smaller x, the applicability of the hard pQCD description somewhat improves, still the soft–hard decomposition of the gluon density shown in Fig. 33 indicates that the nonperturbative soft component of the gluon density remains substantial at gluon momentum squared $\kappa^2 \lesssim 1$–2 GeV^2. According to the discussion in Section 4.8 (see especially Fig. 19), in order to have the hard scale $\overline{Q}^2 \gtrsim 1$–2 GeV^2, one needs $Q^2 \gtrsim 10$ GeV^2. The ρ-production at smaller Q^2 is

Fig. 33. The spin density matrix elements for proton-dissociative J/ψ production as a function of $-t$ measured by H1 [79]. The predictions from the BFKL (solid curves) and pQCD two-gluon approximations (dashed curves) are shown for a comparison [261].

though, since the unintegrated gluon density in the soft region has been adjusted to reproduce real photoabsorption and DIS at small Q^2. At $Q^2 \gtrsim 10$ GeV^2, there is very good agreement between experimentally observed and predicted Q^2-dependence. In the nonperturbative region, the Coulomb WF is doing a better job at the small Q^2, but at the higher Q^2, the experimental data deviate from the curve for the Coulomb WF and agree better with the results for the oscillator WF.

The similar pattern is seen in the ϕ-production shown in Figs. 36 and 37. The preliminary high-$\overline{Q}^2$ data shown in Fig. 37 do agree better with the $k_\perp$-factorization results for the oscillator WF.

Finally, the experimental results for J/ψ are shown in Fig. 38. These data correspond to a sufficiently large hard scale $\overline{Q}^2$. Correspondingly, once the theoretical curves are normalized to the photoproduction data as shown in the bottom plot of Fig. 38 (here, we chose a normalization to the ZEUS point), the curves for the oscillator and Coulomb wave functions become indistinguishable and the resulting description of the experimentally observed Q^2-dependence is very good.

A parametrization of the Q^2 dependence of the recent ZEUS data [90] on the J/Ψ cross section in the same form as (176) with an appropriate change of the meson mass yielded $n_{J/\psi} = 2.44 \pm 0.08$ [84]. The impact of the mass term in $\overline{Q}^2$ on the exponent n_V is substantial, which is well illustrated by the H1 analysis [87] of the combined H1 and ZEUS data on different vector mesons. A fit performed on the H1 and ZEUS ρ data using the parametrization

strongly affected by nonperturbative physics. Still, we notice that the $k_\perp$-factorization predictions [54, 55] reproduce within the overall normalization factor ~2 the measured cross section, which drops by nearly four orders of magnitude from the real photoproduction to the largest value of Q^2. One must not be jubilant,
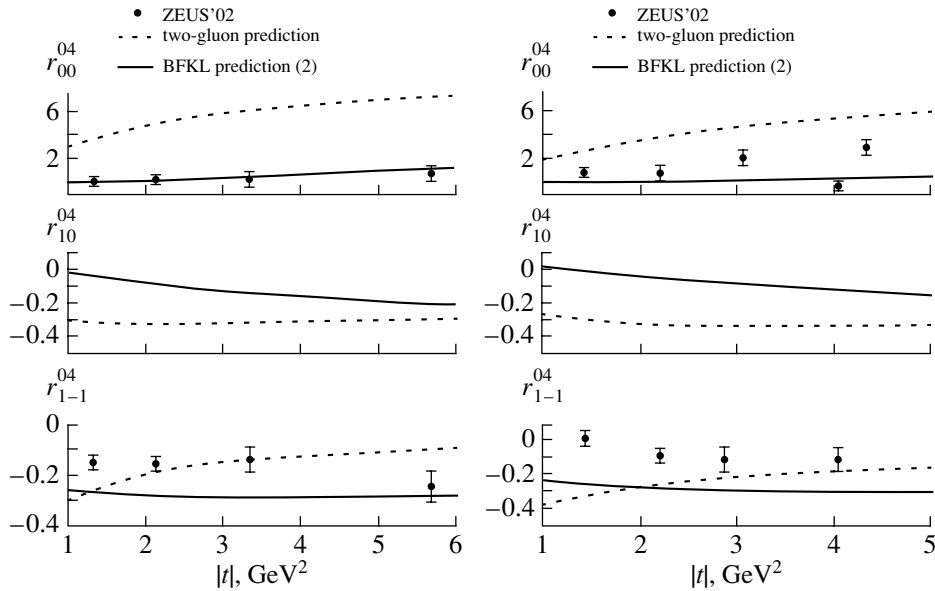

Fig. 34. The spin density matrix elements for proton-dissociative ρ (left box) and ϕ (right box) production as a function of $-t$ measured by ZEUS [77]. The predictions from the BFKL (solid curves) and pQCD two-gluon approximations (dashed curves) are shown for a comparison [261].
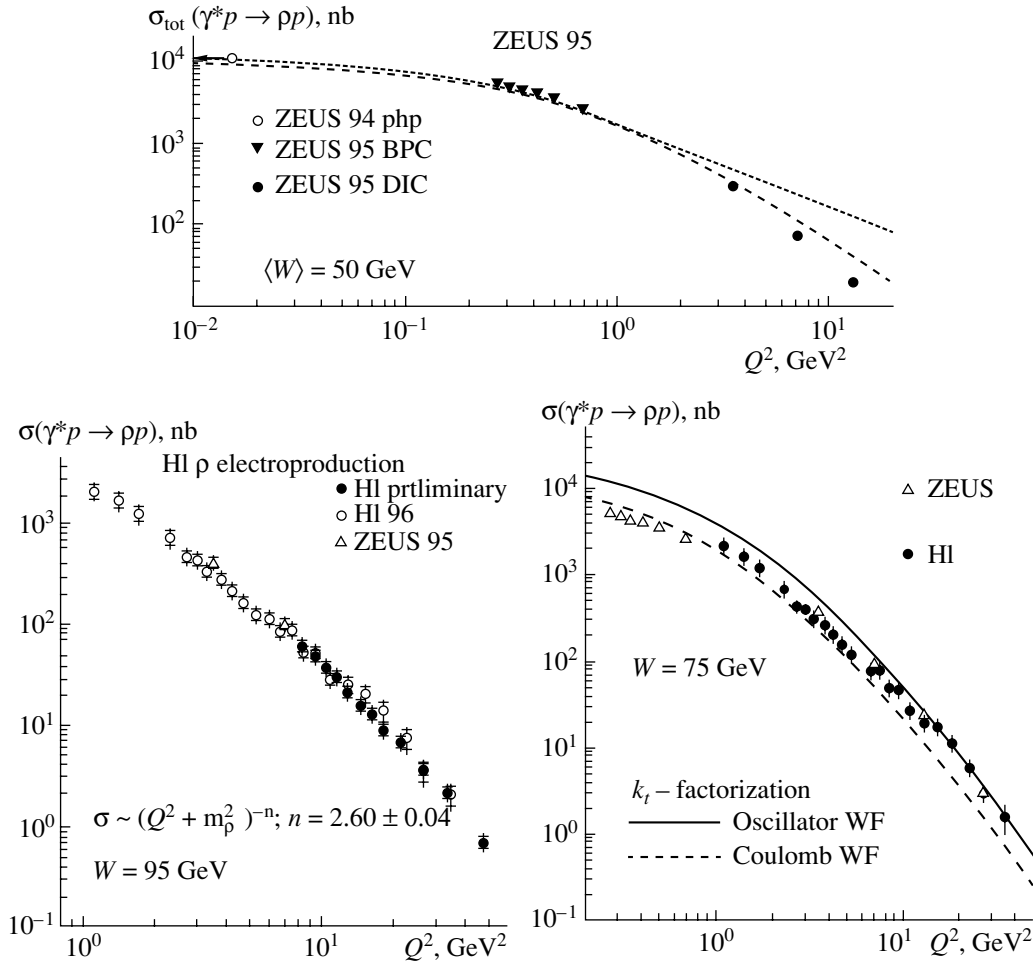

Fig. 35. The total cross section of diffractive ρ meson production as a function of Q^2. Upper plot shows ZEUS data from [81] fitted together with photoproduction point [68]. The curves represent fits using the function $\sigma(Q^2) \propto (1 + R(Q^2))/(Q^2 + m_{\mathrm{eff}}^2)^2$ (dotted curve) and function $\sigma(Q^2) \propto 1/(Q^2 + m_\rho^2)^n$ (dashed curve). The left bottom plot shows recent H1 data [85] compared with published data [16, 81]. The right bottom plot presents the k_t-factorization predictions [54, 55] based on the oscillator (solid curve) and Coulomb (dashed curve) wave functions compared with the published H1 and ZEUS points.

$$\sigma_\rho(Q^2) \propto \frac{a_1}{\left(Q^2 + M_V^2 + a_2\right)^{a_3}} \qquad (177)$$

with the result $a_1 = 10\,689 \pm 165$ nb, $a_2 = 0.42 \pm 0.09$ GeV^2, and $a_3 = 2.37 \pm 0.10$ is shown in a curve in Fig. 39. Notice that the so-found exponent a_3 is close to the recent ZEUS result $n_{J/\psi} = 2.44 \pm 0.08$. The $Q^2 + M_V^2$ dependence of the H1 data on ϕ and of the combined H1 and ZEUS data on J/ψ were found to follow the same parametrization as shown in Fig. 39.

6.1.4. The vector meson production as a probe of the gluon density in the proton. The deceptively simple Eq. (174) suggests that vector meson production cross section discriminates among the different models for the gluon density $G(x_g, \overline{Q}_G^2)$. Ryskin was the first to make

this point [22] (for the early discussion, see [173]). As we saw above, in all the cases, the color dipole/k_t-factorization model with the unintegrated glue adjusted to the proton structure function data is working well on the Q^2-dependence of $\sigma_V(Q^2)$. The $k_\perp$-factorization results for $\sigma_V(Q^2)$ for the two extreme parametrizations of the wave function are shown in Figs. 35, 36, and 38. The choice of the wave function has a marginal impact on the predicted Q^2-dependence. The two curves do typically envelop the experimental data points, but a mismatch of the factor ~2 in the overall normalization between the theory and experiment cannot be eliminated at the moment.

Here, we illustrate the model dependence with the following example. Recent ZEUS data on J/Ψ electroproduction were compared in [90] with the predictions of the three pQCD models by (i) the extended Bloom–
Fig. 36. The published H1 [87] and ZEUS [278, 280] data on the total cross section of diffractive ϕ meson production as a function of Q^2. The k_t-factorization predictions [54, 55] for the oscillator (solid curve) and Coulomb (dashed curve) wave functions are shown for comparison.

Fig. 37. The preliminary ZEUS data [88] on the ϕ meson production cross section are shown together with the published data shown in Fig. 36.

Gilman duality [216] based estimates by Martin *et al.* (MRT [221]) for different NLO DGLAP parametrizations of the gluon density (making use of the NLO gluon densities with leading-order impact factors is somewhat inconsistent, though): MRST02 [284], CTEQ6M [285], and ZEUS-S [286]; (ii) leading $\log Q^2$ estimates with nonrelativistic J/Ψ wave function by Frankfurt *et al.* (FKS [239, 240]) for CTEQ4L gluon density [142]; and (iii) the color dipole model with unitarity corrections by Gotsman *et al.* (GLLMN [287]).

For the heavy J/Ψ, the pQCD scale $\overline{Q}^2$ is already sufficiently large for real photoproduction. The results are shown in Fig. 40. After the absolute normalization is adjusted to the photoproduction point, the resulting Q^2 dependence is not much different from the $k_\perp$-factorization results shown in Fig. 38 and is consistent with the experimental data. The renormalization factors vary from 0.9 for the GLLMN model to 2.98 for the MRT model with the MRST02 gluon density. One would conclude that the predictions for Q^2-dependence from pQCD master formula (174) are to a large extent model-independent ones. Fortuitous models with good reproduction of the absolute value of $\sigma_V(Q^2)$ would not be a wonder, but one should not rejoice with that and, in general, must be content if the theoretical and experimental values of $\sigma_V(Q^2)$ agree within ~50%. Hereafter, we only shall show the $k_\perp$-factorization results [54, 55] for the oscillator parametrization of the wave functions.

6.2. The Flavor Dependence: Ratios σ_V/σ_ρ

The mass term in the scanning radius (8) and the corresponding hard scale $\overline{Q}^2$ of Eq. (9) change dramatically from the ρ, ω to ϕ to J/Ψ. For this reason, a comparison of $\sigma_V(Q^2)$ for the different vector mesons as a function of Q^2 makes no sense. This is clearly seen from Fig. 41, which shows the ratios of cross sections $\sigma_V(Q^2)/\sigma_\rho(Q^2)$ as a function of Q^2. They exhibit a very steep dependence on Q^2 from real photoproduction to large Q^2: even for the ϕ, the ratio rises by a factor of ≈ 3, whereas, for the J/Ψ, it rises by more than two orders of magnitude. The experimentally observed Q^2-dependence is well reproduced within the $k_\perp$-factorization approach [55].

We reiterate the point of Section 6.1 concerning the approximate restoration of flavor symmetry if the cross sections are scaled by the nonrelativistic factor $m_V\Gamma(V \longrightarrow e^+e^-)$ and compared at an equally hard scale $\overline{Q}^2$, i.e., at equal $(Q^2 + m_V^2)$. According to the Review of Particle Properties [102],

$$\frac{1}{\eta_V^{J/\Psi}} = \frac{m_V\Gamma(V \longrightarrow e^+e^-)}{m_{J/\Psi}\Gamma(J/\Psi \longrightarrow e^+e^-)} \quad (178)$$

$$= \rho : \omega : \phi : J/\psi = 0.32 : 0.029 : 0.077 : 1$$

(the uncertainties in the right-hand side of (178) from the decay widths vary from several to ~7% for light to heavy mesons and are not shown).

The J/ψ has been chosen as a reference point as it is the best approximation to a nonrelativistic quarkonium; for light vector mesons, the nonrelativistic approximation is evidently poor. As a test of theory, one must rather compare the predictions for the flavor dependence at a sufficiently large $(Q^2 + m_V^2) \sim 20$ GeV^2.

**Fig. 38.** Upper plot shows recent ZEUS results (solid symbols) on exclusive J/ψ electroproduction cross section as a function of Q^2 at $\langle W \rangle = 90$ GeV [90]. ZEUS photoproduction [71] and H1 electroproduction (open symbols) [89] cross sections are also shown. The full curve is a fit to the ZEUS data of the form (176). The inner error bars represent the statistical uncertainties; the outer bars are the statistical and systematic uncertainties added in quadrature. The bottom plot shows the k_t-factorization predictions [54, 55] based on oscillator (solid curves) and Coulomb (dashed curves) wave functions compared with the published data. The solid curve is the $k_\perp$-factorization result upon the normalization to the photoproduction point with the rescaling factors shown in the figure; the curves for two wave functions merge within the thickness of curves.

Here, the $k_\perp$-factorization predictions can be summarized as

$$\left.\frac{1}{\eta_V^{J/\Psi}}\right|_{k_\perp\text{-fact}} = 0.68 : 0.068 : 0.155 : 1. \qquad (179)$$

There is a marginal change from the oscillator to Coulomb parametrization for wave functions; the theoretical uncertainty in the right-hand side of (179) is about 10%. In Fig. 42, we plot the flavor-rescaled $\sigma_V(Q^2)\eta_V^{J/\Psi}\big|_{k_\perp\text{-fact}}$ for all vector mesons as a function of $(Q^2 + m_V^2)$. The universal $(Q^2 + m_V^2)$-dependence is clearly seen, and the overall agreement between the experimentally observed and theoretically predicted flavor dependence is good.

For uncertain reasons, perhaps because of misinterpretation of the discussion in [239], one often discusses the restoration of the $SU(4)$ flavor symmetry,

$$\rho^0 : \omega : \phi : J/\psi = 1 : 1/9 : 2/9 : 8/9 \qquad (180)$$
$$= 1.125 : 0.125 : 0.22(2) : 1.$$

Incidentally, it is not much different from (179), except of J/ψ (see Fig. 41). We caution that there are no sound reasons for such a $SU(4)$ ratio of cross sections even at very large Q^2. The $SU(4)$-factor weighted empirical cross sections were shown in Fig. 39 and can indeed be fitted by the flavor-independent universal curve, but this agreement with $SU(4)$ ratios must be regarded as an accidental one.

6.3. The Ratio $R_V = \sigma_L/\sigma_T$

6.3.1. Theoretical expectations. For heavy vector mesons treated as a nonrelativistic quarkonium, the pQCD predicts $R_V(Q^2) = \dfrac{Q^2}{m_V^2} R_{LT}$ with $R_{LT} = 1$ (see (148)).

Despite all the uncertainties with the wave functions, an important point is that, for a meaningful evaluation of $R_V(Q^2)$, the transverse and longitudinal vector meson must be related by the rotation invariance. The Fermi motion effects, in the longitudinal and transverse amplitudes, are different, though, the latter being more sensitive to the endpoint contributions from $z \sim 0$, $z \sim 1$. Such corrections are automatically incorporated in the color dipole and $k_\perp$-factorization calculations. First, as discussed in Section 4.8, the hard pQCD scales for transverse and longitudinal cross sections do slightly differ, $\overline{Q}_{GT}^2 \lesssim \overline{Q}_{GL}^2$, which already leads to a substantial reduction of R_{LT} at large Q^2, as was found in [21]. Second, the SCHNC transitions contribute for the most part to the transverse cross section, especially for light vector mesons, further lowering R_{LT}. Third, as discussed in Section 4.10, the predictions for $R_V(Q^2)$ are potentially very sensitive to the presence of a hard, quasi-pointlike $q\bar{q}$ component in the vector meson wave function. As a test of this sensitivity, we evaluate $R_V(Q^2)$ for a squeezed ρ-meson, as discussed in Section 4.10.

One way to circumvent problems with the poorly known wave function of vector mesons is to resort to the Bloom–Gilman duality for diffractive DIS [216]. Because of the strikingly different dependence of the duality integrals for σ_L, σ_T on the duality interval (see Eqs. (94), (95)), the ability [220, 221] to reproduce both $\sigma_V(Q^2)$ and $R_V(Q^2)$ is not surprising. It is not clear, though, whether such an evaluation is entirely consistent with the rotation invariance constraints or not.

In the color evaporation model discussed in Section 3.4.7, the J/Ψ is a part of the open charm cross section and, arguably, the ratio σ_L/σ_T must be close to that for the open charm, $R_V \approx R_{\text{DIS}} \ll 1$, which would conflict with the large-Q^2 data on J/ψ production shown below.

*6.3.2. Experimental results.* Figure 43 shows the ratio

Fig. 39. H1 and ZEUS measurements [16, 68, 70, 75, 80, 81, 89, 278, 280–283] of the total cross sections $\sigma(\gamma^*p \longrightarrow Vp)$ as a function of $(Q^2 + M_V^2)$ for elastic ρ, ω, ϕ, J/ψ, and Υ meson production, at the fixed value $W = 75$ GeV. The cross sections were scaled by $SU(5)$ charge-isospin factors. The curve is a fit by formula (177) to the H1 and ZEUS ρ data, and the ratio D of the scaled ω, ϕ, and J/ψ cross sections to this parametrization is presented in the insert.

$$R_\rho(Q^2) = \frac{\sigma_L(\gamma^*p \longrightarrow \rho p)}{\sigma_T(\gamma^*p \longrightarrow \rho p)}$$

as a function of Q^2 for the ρ meson production. The right plot shows the same data presented in the form of

$$R_{LT}^\rho(Q^2) = R_\rho(Q^2)\frac{m_\rho^2}{Q^2}.$$

At the small values of Q^2, the ratio is approximately a linear function of Q^2 and $R_{LT}(0) \sim 1$, but $R_{LT}(Q^2)$ decreases steadily with rising Q^2 and the growth of $R_\rho(Q^2)$ slows down. Whereas some of the published data sets even suggest flattening of $R_\rho(Q^2)$, the new preliminary data [83, 85] indicate the steady large-Q^2 rise of $R_\rho(Q^2)$.

The dotted curve shows an evaluation $R_\rho(Q^2)$ [220, 221] based on the duality approach [216]. Whereas, in the $k_\perp$-factorization, one starts with the $q\bar{q}$ continuum production amplitudes, projects it onto the $J^P = 1^-$ state, and averages over the masses $M \sim m_V$ of

the $q\bar{q}$ state with the vector meson wave function as the weight function. In the duality approach [216], one rather calculates $|\mathcal{T}|^2$ for a fixed diffractive mass M and then integrates over a certain range of M around m_V. For the ρ meson, Martin *et al.* takes the duality interval $M = [M_1, M_2] = [600, 1050]$ MeV. Because of the different sensitivity of duality integrals for $\sigma_{L,T}$ to the duality interval (see Eqs. (93), (95)), one readily finds a good description of the Q^2 dependence of $R_\rho(Q^2)$ and the expense of a possible conflict with the rotation invariance. Although the absolute value of $R_\rho(Q^2)$ is essentially adjusted to the data, the steady rise of $R_\rho(Q^2)$ at large Q^2 must be regarded as the genuine pQCD prediction (for uncertainties with the duality description of the absolute cross section, see Section 3.4.7).

The solid curve shows the result of the $k_\perp$-factorization calculation with the conservative radius of the ρ-meson. Although, at largest $Q^2 \sim 20$ GeV^2, the predicted $R_{LT} \sim 0.3 \ll 1$, as already found in 1994 within the color dipole model [21], there is an obvious dis-
Fig. 40. The recent ZEUS data on Q^2-dependence of J/ψ electroproduction at $\langle W \rangle$ = 90 GeV [90]. The curves in the top box represent the predictions of the QCD models MRT FKS and GLLMN (see text); the curves in the bottom plot are the MRT results based on different gluon densities in the proton. All theoretical curves are rescaled as indicated to fit the ZEUS photoproduction point at $\langle W \rangle$ = 90 GeV. The inner error bars represent the statistical uncertainties; the outer bars are the statistical and systematic uncertainties added in quadrature. An overall normalization uncertainty of $^{+5\%}_{-8\%}$ was not included.

agreement with the large-Q^2 data. A comparison between the data and the k_t-factorization calculations in terms of σ_L and σ_T separately shows [54] that the source of this discrepancy is the transverse cross section σ_T, whose value at high Q^2 is significantly underestimated by the model. A strong sensitivity of predictions for $R_\rho(Q^2)$ to the short-distance properties of the vector meson is illustrated by the dotted curve which is the $k_\perp$-factorization result for the squeezed ρ-meson. As anticipated in Section 4.10, the prime effect of higher short-distance density in the ρ-meson is an enhancement of σ_T and suppression of $R_\rho(Q^2)$.

Figure 44 shows the ratio σ_L/σ_T for the J/ψ mesons compared with the prediction of the k_t-factorization model. The recent ZEUS result averaged over Q^2 is $R_{LT} = 0.52 \pm 0.16$ [90]. The recent high-accuracy experimental results for large-Q^2 ϕ production are shown in Fig. 45. If compared against equal Q^2/m_V^2, the theoretical results and the experimental data for R_{LT} show similar behavior for all three vector mesons: ρ, ϕ, and J/ψ. For instance, the fit to experimental data on r_{00}^{04} for the

ρ-production shown in Fig. 25 can be reinterpreted, via Eq. (164) with $\epsilon \approx 1$, as $R_\rho = a(Q^2/m_\rho^2)^b$ with $a = 1/\xi = 0.46 \pm 0.015$ and $b = k = 0.75 \pm 0.3$ which perfectly agrees with the recent ZEUS parametrization for the ϕ production shown in Fig. 45: $a = 0.51 \pm 0.07$ and $b = 0.86 \pm 0.11$.

7. THE ENERGY DEPENDENCE AND REGGE PROPERTIES OF DIFFRACTIVE VECTOR MESON PRODUCTION

7.1. Theoretical Expectations

The local energy dependence of $\sigma_{\gamma^*p \to Vp}(W^2, Q^2)$ is usually parametrized as

$$\sigma_{\gamma^*p \to Vp}(W^2, Q^2) \propto W^\delta. \qquad (181)$$

The exponent δ for the t-integrated total cross section is controlled by the x-dependence of the integrated gluon density (see Eq. (145)) and the shrinkage of the diffraction cone. Within the standard exponential approximation for the t-dependence,

$$\sigma_{\gamma^*p \to Vp}(W^2, Q^2) \propto \frac{\operatorname{Im} \mathcal{T}_{LL}^2(W^2, t = 0)}{W^4 b_V(W^2, Q^2)} \qquad (182)$$

and

$$\delta = 4\left[\lambda(\overline{Q}_G^2) - \frac{\alpha'_{IP}}{b(\overline{Q}_G^2)}\right]. \qquad (183)$$

The microscopic pQCD models of the Pomeron exchange (see Sections 3.2 and 3.3 and Eq. (60)) suggest that the Pomeron is a more complex object than an isolated single pole; it is either the branching point or a sequence of Regge poles. For this reason, the exponent δ can depend on Q^2, m_V, the energy range, helicities, etc. Equation (183) emphasizes the crucial point [21] that within the color dipole and $k_\perp$-factorization approaches, δ only depends on $\overline{Q}_G^2 \sim (Q^2 + m_V^2)$. The corrections to the $(Q^2 + m_V^2)$-scaling are well understood and marginal: a slight departure of the hard scale $\overline{Q}_G^2$ from $\overline{Q}^2$ has been discussed in Section 4.8. Specifically, at equal values of $Q^2 + m_V^2$, the ρ production is in a somewhat softer regime than the J/ψ production, and one can expect that $\delta_{J/\psi}$ should be slightly larger than for the δ_ρ.

The $k_\perp$-factorization phenomenology of DIS structure functions described in Section 3.3.3 strongly suggests that for purely numerical reasons, within the kinematical range of the HERA experiments, the vacuum exchange can be approximated by the two, soft and hard, Pomeron poles with approximately Q^2-independent intercepts. The values of the intercepts anticipated in this approximation were given in Sections 3.1.4 and 3.3.
Fig. 41. The ratios of the ω [86], ϕ [87] (the PHP point is calculated using [68, 278]), and J/ψ (calculated using only recent ZEUS data [68, 71, 81, 90]; for H1 results, see Figs. 42, 77) to the ρ^0 cross sections as a function of Q^2. The horizontal solid curves correspond to the $SU(4)$ predictions, while the horizontal dashed curves correspond to the pQCD predictions in the nonrelativistic approximation given by Eq. (178). As shadowed band, the corresponding predictions from the k_t-model for the oscillator wave functions [55] are shown. The width of the band is taken just arbitrary and does not correspond to the theoretical uncertainties. The k_t-model prediction for the $J/\psi/\rho$ ratio at $Q^2 = 100$ GeV^2 is shown separately as a dash–dotted curve.

They translate into $\delta \sim 0.2$–0.4 in the soft region and much larger $\delta \gtrsim 1$–1.5 when the interaction becomes sufficiently hard. Since the pQCD hard scale $\overline{Q}^2$ increases not only with Q^2, but also with m_V, the theory predicts the corresponding hierarchy $\delta_{J/\psi} > \delta_\phi > \delta_\rho$ at any Q^2, including photoproduction (for exact values, see Fig. 46). On the other hand, the variations of δ from ρ, ω to ϕ to J/Ψ to Υ are weak against the variable $Q^2 + m_V^2$.

The energy dependence of the $\psi(2S)$ production should be discussed separately. As pointed out in Section 3.4.3, the node of the $2S$ radial wave function leads to a partial compensation between contributions from dipoles with a size, below and above, the node. As a result, the typical dipole sizes that contribute to $\psi(2S)$ production are smaller than for J/ψ production. This makes the pQCD scale for $\psi(2S)$ production somewhat harder than for J/ψ, which results in $\delta_{\psi(2S)} > \delta_{J/\psi}$ and the

rise of the cross section ratio $\sigma(\psi(2S))/\sigma(J/\psi)$ with growing energy is predicted [26, 54].

7.2. Experimental Results: Real Photoproduction

7.2.1. Ground-state vector mesons. The summary of the experimental data on the energy dependence of all vector meson photoproduction cross sections measured at HERA is shown in Fig. 47 together with the total cross section $\sigma_{\text{tot}}^{\gamma p}$ and the results from fixed-target experiments. There is a clear pattern of variation of the exponent δ from light to heavy mesons: for the light vector mesons, ω, ρ, and ϕ, the rise of the cross sections with energy is well described by $W^{0.22}$ behavior. Already the first measurement of the J/ψ photoproduction at HERA showed a much steeper rise with W than that observed for the light vector mesons. The energy dependence was found to be $W^{(0.7–0.8)}$, which implies the effective Pomeron intercept around $\alpha_{IP}(0) \approx 1.2$.

**Fig. 42.** A compilation of the flavor-rescaled using $k_\perp$-factorization Eq. (179) total cross sections $\eta_V^{J/\psi}\sigma_V(Q^2)$ for the ρ, ω, ϕ, J/Ψ vector mesons [16, 68, 71, 81, 86, 87, 89, 90, 278, 280, 288] as a function of $Q^2 + m_V^2$. Also shown are the corresponding predictions from the k_t-model for the oscillator wave functions [55].

The still larger δ has been found for $\Psi(2S)$, the experimental data on Υ production are not yet conclusive. Figure 48 summarizes the experimental data on the ρ photoproduction, while Fig. 49 shows the recent ZEUS photoproduction measurement [71] of the J/ψ photoproduction in a wide W range (20–300 GeV) together with earlier data from H1 and fixed-target experiments. The result of the fit in the form $\sigma \propto W^\delta$ to the ZEUS data with $W > 30$ GeV yielded $\delta = 0.69 \pm 0.02(\text{stat.}) \pm 0.03(\text{syst.})$.

The k_t-factorization and color dipole calculations, shown in Fig. 46, precisely predict such a variation of the energy dependence with the mass of the vector meson. The real photoproduction of light vector mesons is dominated by a nonperturbative component of the unintegrated gluon density of the proton and/or soft dipoles, and δ is small, but the contribution from hard gluons rises from light to heavy vector mesons, which is a universal prediction from all pQCD motivated models. The energy dependence from the specific $k_\perp$-factorization model [54, 55] comes out right for both ρ (Fig. 48) and J/Ψ mesons (Fig. 49).

7.2.2. Radially excited vector mesons. The $\Psi(2S)$ photoproduction was studied by H1 [73] using tagged and untagged data samples of $\Psi(2S) \longrightarrow ll$ and $\Psi(2S) \longrightarrow ll\pi\pi$ decay channels, where ll stands for e^+e^- or $\mu^+\mu^-$. The measurement of the ratio R of $\Psi(2S)$ to J/ψ photoproduction cross sections, as a function of W, is shown in Fig. 50. The suppression of this ratio, $R \ll 1$, is due to the node effect; the resulting strong cancellations between the contribution from large-size and small-size components of the $\Psi(2S)$ make the predicted ratio strongly dependent on the model for the wave function. The experimental data agree with k_t-factorization predictions based on the oscillator wave function.
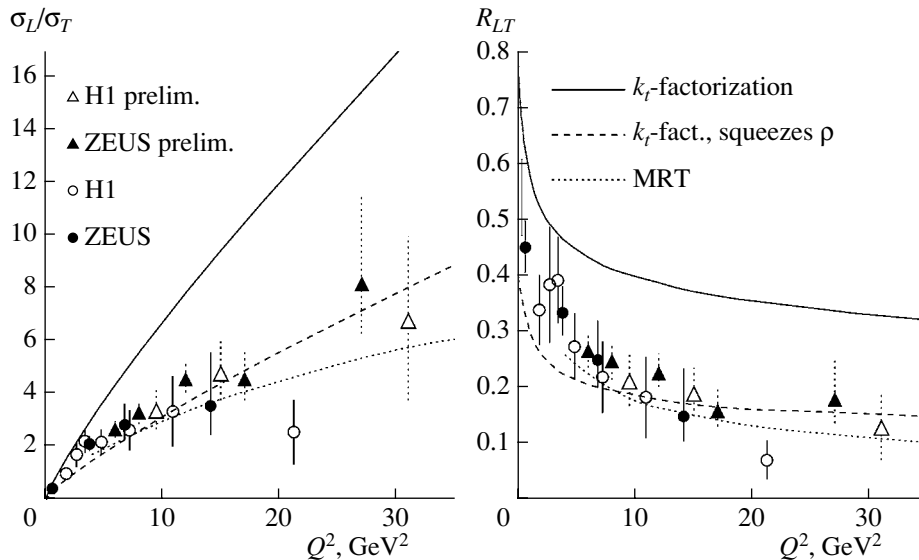

Fig. 43. A compilation of the experimental data on the ratio $R_\rho = \sigma_L/\sigma_T$ and $R_{LT}^\rho = R_\rho m_\rho^2/Q^2$ for the ρ meson production as a function of Q^2. The recent preliminary data from H1 [85] and ZEUS [83] measurements are just scanned from the plots of the correspondent papers and shown together with the published results [16, 68, 81, 277]. The theoretical predictions are as follows: the dotted curve shows the estimates by Martin *et al.* based on the Bloom–Gilman duality [220]; the solid curve and dashed curves show the results from the $k_\perp$-factorization for the conservative radius of the ρ-meson and the squeezed ρ-meson, respectively [54, 55].
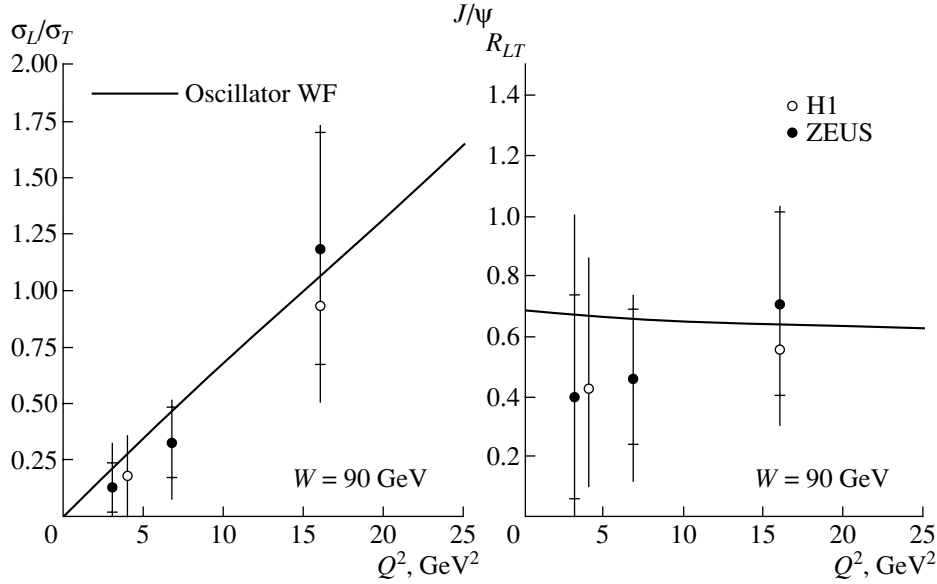

Fig. 44. A compilation of the experimental data on the ratio $R_{J/\psi} = \sigma_L/\sigma_T$ and $R_{LT}^{J/\psi} = R_{J/\psi} m_{J/\psi}^2/Q^2$ for the J/ψ meson production as a function of Q^2. The open circles represent the H1 [89], and solid symbols, the ZEUS J/ψ measurements [90]. The solid curve is a prediction from the $k_\perp$-factorization approach [55].

The overall ratio for the data gives the value $R = 0.166 \pm 0.007$(stat.) $\pm$ 0.008(syst.) $\pm$ 0.007(BR), which is in good agreement with previous measurements [72] (for the branching error calculation, see [73]). A fit to this ratio of the form $R \propto W^{\Delta\delta}$ yields $\Delta\delta = 0.24 \pm 0.17$, which indicates that the energy dependence of the $\Psi(2S)$ photoproduction cross section is slightly steeper than that for the J/ψ meson. This agrees with the color dipole model expectations [26, 49].

The definitive $\rho'(2S)$ assignment of the excited ρ states is still pending, and the experimental data on the $\rho'(2S)$ production are not yet available. Here, we simply mention that all color dipole [178, 181, 182] and/or $k_\perp$-factorization [54, 55] calculations based on the node effect predict $\sigma(\rho'(2S))/\sigma(\rho(1S)) < 1$ with very steep Q^2 dependence up to $Q^2 \gtrsim 3$–5 GeV^2, whereas the duality relation estimates by Martin *et al.* [220] gives $\sigma(\rho'(2S))/\sigma(\rho(1S)) > 1$. This simply shows that one must be careful with the application of duality to radial excitations, because the mass spectrum of the $q\bar{q}$ pairs that enters the duality integral does not exhibit any non-monotonous Q^2-dependence [3, 217], the steep Q^2-dependence driven by the node effect can easily be missed.

7.2.3. Test of the vector dominance model. In the color dipole language, the success of the vector-dominance model (VDM) for real photoproduction derives from the proximity of the (quark flavor-dependent) color dipole distributions in the photon and light vector mesons. The straightforward extension of the VDM approximation (67) to the γp elastic scattering amplitude reads

$$\mathcal{T}(\gamma p \longrightarrow \gamma p) = \sum_{V = \rho, \omega, \phi} \frac{\sqrt{4\pi\alpha_{em}}}{f_V} \mathcal{T}(\gamma p \longrightarrow Vp). \quad (184)$$

Assuming the pure imaginary amplitudes, which is a good approximation because, in real photoproduction, $\frac{1}{4}\delta \ll 1$, one can extract the photoproduction amplitudes from the forward differential cross sections,

Fig. 45. A compilation of the experimental data on the ratio $R_\phi = \sigma_L/\sigma_T$ for the ϕ meson production as a function of Q^2. Shown are the recent preliminary data from ZEUS [88] together with the published results from ZEUS [278, 280] and H1 [87]. The solid curve shows the fit of the form $R_\phi = a(Q^2/m_\phi^2)^b$ with the parameters cited in the figure.
Energy rise exponent δ

Fig. 46. The k_t-factorization predictions for the exponent δ of the fits $\sigma \propto W^\delta$ to the W dependence for different vector mesons [54, 55]. Notice a strong flavor dependence in the left box where δ is plotted as a function of Q^2. The flavor dependence is much weaker when δ is plotted against $Q^2 + M_V^2$ (right box).

whereas the γp elastic scattering amplitude is related by optical theorem to $\sigma_{\text{tot}}(\gamma p)$. This leads to the Stodolsky sum rule [291]:

$$\sigma_{\text{tot}}(\gamma p) = \sqrt{16\pi \frac{d\sigma^{\gamma p \to \gamma p}}{dt}\bigg|_{t=0}}$$

$$= \sum_{V=\rho^0, \omega, \phi} \sqrt{16\pi \frac{4\pi\alpha}{f_V^2} \frac{d\sigma^{\gamma p \to Vp}}{dt}\bigg|_{t=0}}. \tag{185}$$

The test of the VDM sum rule has been reported by the ZEUS Collaboration [292]. The VDM analysis of the low-energy data gave $f_V^2/4\pi = 2.20$, 23.6, and 18.4 [42] for ρ^0, ω, and φ, respectively. Then, based on the photoproduction data at 70 GeV, the VDM sum rule gives a value of 111 ± 13(exp.) μb for the photon–proton total cross section at $W_{\gamma p} = 70$ GeV. The ρ^0 meson contributes about 85% of this value. The interpolation of photon–proton total cross section at a center-of-mass energy of $W_{\gamma p} = 70$ GeV, obtained by interpolation between the present measurement and the lower-energy measurements using the Regge model fits, is 139 ± 4 μb. The two numbers are close to each other; the point that simplified the VDM model, that it does not saturate the sum rule, is well known (for the review, see [42]).

7.3. Experimental Results: Vector Mesons in DIS

7.3.1. The impact of hard scale on energy dependence. The cross section for the exclusive ρ^0 electroproduction measured by ZEUS [83] and H1 [85], as a function of W for different values of Q^2, is presented in Fig. 51. The curves represent the result of the $\sigma \propto W^\delta$

fits to the data. The exponent of energy dependence increases with the Q^2 growth from about 0.2 at low Q^2 up to 0.8–1.0 at high Q^2, in agreement with theoretical expectations from the color dipole approach shown in Fig. 46. In contrast to the ρ production, the J/ψ production cross section exhibits almost the same W-dependence for all measured values of Q^2, including the photoproduction limit (see Fig. 52), in good agreement with the theoretical prediction from the color dipole approach shown in Fig. 46.

The point that the correct hard scale is $\propto (Q^2 + m_V^2)$ is clear from Fig. 53, which shows the dependence of the exponent δ on Q^2 (the left-hand side box) and ($Q^2 + m_V^2$) (the right-hand side box), respectively. For the ρ-mesons, both plots give a clear indication of the rise of δ with Q^2 and $\overline{Q}^2$. At largest Q^2, the exponent δ rises up to 1–1.2, implying the rise of the effective intercept of the Pomeron up to $\alpha_P(0) \approx 1.3$. If it were to be plotted as a function of Q^2, the exponent δ for the J/Ψ would be completely out of the observed trend for the ρ-meson (see the left-hand side box, where only the PHP point is shown). When plotted as a function of ($Q^2 + m_V^2$), the same result for the J/Ψ is perfectly consistent with the results for the ρ at the same value of ($Q^2 + m_V^2$), confirming with the theoretical expectation of the (approximate) flavor symmetry in this variable. The theoretical values of δ shown in Fig. 53 were evaluated for the range $W = 50$–100 GeV. The overall agreement between the experiment and $k_\perp$-factorization approach is good. The lower box of Fig. 52 shows the k_t-factorization predictions [54, 55] normalized to the ZEUS photoproduc-
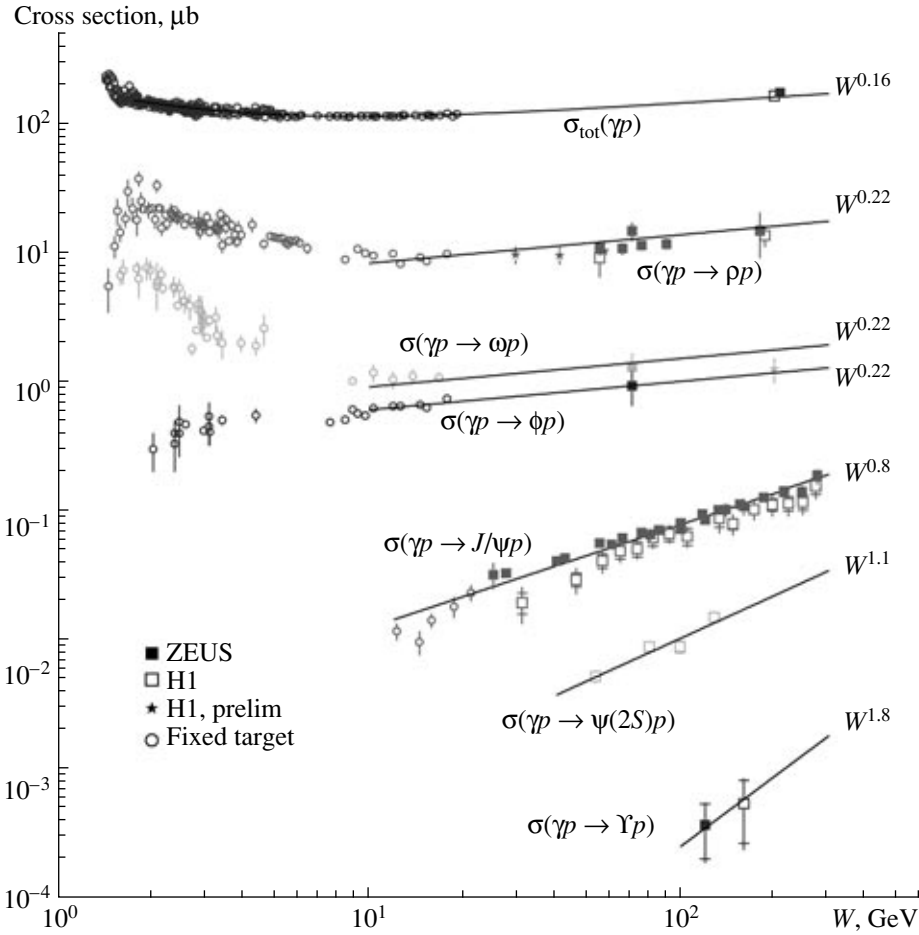

Fig. 47. The total vector-meson photoproduction cross section as a function of W for all vector mesons measured at HERA shown together with the results of fixed target experiments and compared with the total photoabsorption cross section $\sigma_{tot}^{\gamma p}$.

tion cross section at $\langle W \rangle = 90$ GeV; the quality of the theoretical description of the data points is good.

7.3.2. Discriminating the models for gluon density. The earlier discussion of the J/Ψ production was centered around the idea in [22], of model stringent tests for the gluon density $G(x, Q^2)$. An example of such a test based on the experimental data available at that time, is illustrated by the left-hand side plot of Fig. 54. The shown theoretical curves [173] are based on the 1995 updates of parametrizations for the gluon density adjusted to the HERA data on the small-x growth of $F_{2p}(x, Q^2)$. The energy behavior of each vector meson production can also be reproduced by a number of simple parametrizations within models described in Sections 3.1.4 and 3.4.8. An example of a fit to the J/Ψ photoproduction cross section in a model by Fiore *et al.* [229], in which Pomeron is the double-pole at $\alpha_P(0) = 1$, is shown in the right-hand side plot of Fig. 54.

The past decade brought great improvements in our understanding of the small-x gluon densities and in the vector meson production data compared to the 1995 situation shown in Fig. 54. The discrimination of the mod-

els remains weak, though: for the reasons discussed in Section 6.4, there are substantial uncertainties in the absolute normalization, which cannot be eliminated at the moment. This point is further illustrated by the recent ZEUS data on J/Ψ electroproduction shown in Fig. 40 in comparison with the predictions from the more recent MRT, FKS, and GLLMN models for the gluon density described in Section 6.4. All models need large rescaling to adjust the normalization to the photoproduction at $\langle W \rangle = 90$ GeV. At the expense of such rescaling, all model calculations reasonably reproduce the gross features of energy dependence. For comparison, the k_t-factorization predictions [54, 55] shown in the bottom plot of Fig. 52 give an equally good description of the same data using a rescaling factor 0.86. One exception is the MRT results for the MRST02 gluon density for small Q^2; the likely reason for the strong discrepancy found is that the corresponding values of $\overline{Q}^2$ are too close to the lower Q^2-boundary of applicability of this particular set of parton densities [284].
$\sigma(\gamma p \to \rho p)$, μb

Fig. 48. The W-dependence of exclusive ρ photoproduction cross section measured by the H1 [277] and ZEUS [68] experiments compared with predictions of the k_t-factorization model for the oscillator and Coulomb wave functions of the ρ meson.

7.3.3. Comparison of vector meson production and inclusive DIS from regge model viewpoint. We repeatedly made a point that the pQCD vacuum exchange is not an isolated Regge pole. Section 3.3 and Fig. 11 show how the effective exponent of the $\frac{1}{x}$-dependence changes from $\tau(\kappa^2)$ for the unintegrated glue $\mathcal{F}(x, \kappa^2)$ to $\lambda(Q^2)$ for the integrated glue $G(x, Q^2)$ to $\Delta(Q^2)$ for $F_2(x, Q^2)$ or $\sigma_{tot}^{\gamma^* p}(x, Q^2)$. This entails the failure of naive Regge factorization in a comparison of the energy dependence of vector meson production and inclusive DIS, which was nicely demonstrated by ZEUS Collaboration [295] in their study of the ratio

$$r_{tot}^V = \frac{\sigma_{\gamma^* p \to Vp}(W^2, Q^2)}{\sigma_{tot}^{\gamma^* p}(W^2, \overline{Q}^2)}. \tag{186}$$

The argument is as follows. According to Eqs. (181) and (183),

$$\sigma(\gamma^* p \longrightarrow Vp) \propto (W^2)^{2\lambda_{tot}^V(Q^2)}, \tag{187}$$

$$\lambda_{tot}^V(Q^2) = \frac{1}{4}\delta \approx \lambda(\overline{Q}^2) - \frac{\alpha_P'}{b(W^2)} = \alpha_P - \frac{\alpha_P'}{b(W^2)} - 1,$$

where the last form in terms of α_P holds if the QCD Pomeron were an isolated Regge-pole. Notice that $\lambda(Q^2)$ as defined in Section 3.3.1 is different from the exponent $\Delta(Q^2)$ in

$\sigma(\gamma p \to J/\psi p)$, nb
Fig. 49. A compilation of the experimental data on exclusive J/ψ photoproduction cross section as a function of W measured. The black points show the recent ZEUS data for the $J/\psi \longrightarrow \mu^+\mu^-$ and $J/\psi \longrightarrow e^+e^-$ decay channels [71]. The inner bars indicate the statistical uncertainties; the outer bars are the statistical and systematic uncertainties added in quadrature. Results from the H1 [70] and fixed-target experiments [289, 290] are shown by open symbols. Recently, H1 reported about correction of the published cross sections, and they are now much closer to the ZEUS ones. The k_t-factorization predictions [55] for the oscillator and Coulomb wave functions are shown by the solid and dashed curves, respectively.
$R = \sigma_{\psi(25)}/\sigma_{J/\psi}$

Fig. 50. The ratio of photoproduction cross sections $\Psi(2S)$ over J/ψ as a function of W [73]. The k_t-factorization predictions [55] are shown for comparison.
Fig. 51. The W dependence of the ρ electroproduction cross section for different values of Q^2 as measured by ZEUS [83] and H1 [85]. The curves represent the results of fitting $\sigma \propto W^\delta$ with the δ values indicated in the figures. The shaded area in the ZEUS case indicates additional normalization uncertainties due to proton dissociation background.

$$\sigma_{\rm tot}^{\gamma^* p} \propto (W^2)^{\Delta(\overline{Q}^2)} = (W^2)^{\alpha_P - 1} \qquad (188)$$

(see a comparison in Fig. 10). Such a difference between the intercepts $\lambda(Q^2)$ and $\Delta(Q^2)$ and their substantial dependence on Q^2 shown in Fig. 10 already go beyond the rigors of the Regge theory. Still one can try to probe the vacuum exchange in the numerator and denominator of r_V equalizing the relevant hard scales, i.e., evaluating the ratio $r_{\rm tot}^V$ with $\sigma_{\rm tot}^{\gamma^* p}(W^2, \overline{Q}^2)$ taken at $\overline{Q}^2 = (Q^2 + m_V^2)/4$. In Fig. 56, we present $\lambda_{\rm tot}^V(Q^2)$ and $\Delta(\overline{Q}^2)$ plotted vs. common hard scale. Only if one ignored the difference between $\lambda(Q^2)$ and $\Delta(Q^2)$, the W-dependence in (187) and (188) would be controlled by one and the same α_P and one would expect the W-dependence of the ratio $r_{\rm tot}^V$ of the form

$$r_{\rm tot}^V \propto (W^2)^\eta, \quad \eta = \alpha_P - \frac{\alpha_P'}{b(W^2)} - 1. \qquad (189)$$

The experimental results on $r_{\rm tot}^V$ for the ρ and J/Ψ are shown in the left-hand side plots of Fig. 57. They are consistent with little or no W-dependence for the ρ production. Notice that an approximate constancy of r_V for the ρ-production at small Q^2 is very much reminiscent of the familiar very weak energy dependence of the ratio $\sigma_{\rm el}/\sigma_{\rm tot}$ in πN, KN, NN interaction (see plots in [102]). Here, the smallness of the exponent η is to a large extent due to the term $\alpha_P'/b(W^2)$ from the shrinkage of the diffraction cone. The W-dependence of $r_{\rm tot}^V$

for the J/Ψ production is substantial. This hard-scale and process dependence of η has been interpreted as evidence for the breaking of the Regge factorization.

The energy dependence of $r_{\rm tot}^V$ expected from k_t-factorization is shown in the right-hand side boxes of Fig. 57. It includes the effect of shrinkage of the diffraction cone. The theoretical results correctly reproduce the trend of the experimental data shown in left-hand side boxes of Fig. 57. Although, the ZEUS experimental results for the ρ mesons are consistent with $r_{\rm tot}^V = $ const, within the error bars, they do not exclude the theoretically expected weak-energy dependence shown in the right-hand side plot. The $k_\perp$-factorization correctly describes the change of energy dependence of $r_{\rm tot}^V$ from the light ρ to heavy J/Ψ.

8. THE T-DEPENDENCE AND PROPERTIES OF DIFFRACTIVE CONE

8.1. Low-t: Proton-Elastic and Proton-Dissociative Events

The vector meson production differential cross section $d\sigma/dt$ exhibits a pronounced forward diffraction cone, which spans up to $|t| \lesssim 1.0$ GeV^2. Such a diffraction cone is familiar from hadronic scattering processes. Within the diffraction cone, the differential cross section falls off with $|t|$ approximately exponentially (see Sections 3.1.3 and 3.1.4). In close similarity to hadronic scattering, the dominant process here is the proton-elastic (hereafter, just "elastic") production of ground-state vector mesons $\gamma p \longrightarrow Vp$ (see Fig. 58, left), where the label "elastic" is a reminder of the VDM
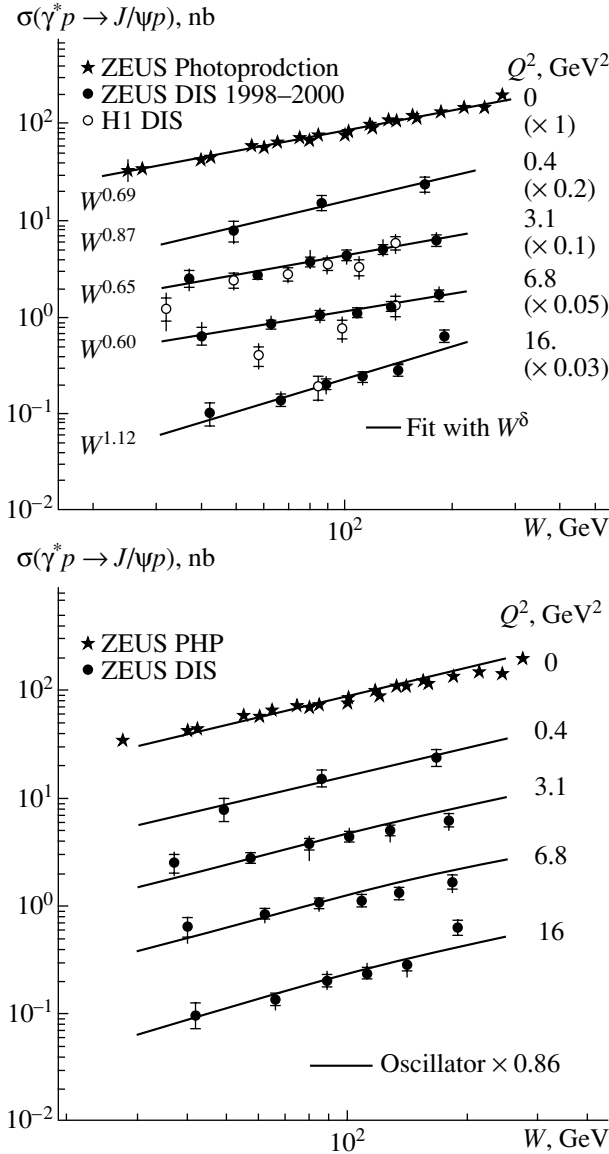

$\sigma(\gamma^* p \to J/\psi p)$, nb

$\sigma(\gamma^* p \to J/\psi p)$, nb

Fig. 52. The top plot shows the recent ZEUS results on exclusive J/ψ electroproduction cross section as a function of W for four values of Q^2 [90]. ZEUS photoproduction [71] and H1 electroproduction [89] cross sections are also shown. The full curves are fits to the ZEUS data of the form $\sigma \propto W^\delta$. The inner error bars represent the statistical uncertainties; the outer bars are the statistical and systematic uncertainties added in quadrature. An overall normalization uncertainty of $^{+5\%}_{-8\%}$ was not included. The bottom plot shows the k_t-factorization predictions [54, 55] normalized to the ZEUS photoproduction cross section at $\langle W \rangle = 90$ GeV and compared to the recent ZEUS data.

relationship between the photoproduction and *VP* elastic scattering amplitude (recall Section 3.4.1).

At larger *t*, the elastic production dies out and the proton-dissociative reaction $\gamma p \longrightarrow VY$ takes over. One can argue [114] that the relative importance of the elastic and proton-dissociative reaction is precisely the

same as in proton–nucleus and proton–proton scattering described in Section 3.1.5. At small *t*, within the diffraction cone, the proton-dissociative production will be smaller than the elastic production but still the biggest background contribution to the elastic vector meson production.

Experimentally, the direct separation of the two processes is only possible if the leading proton is measured in the leading (forward) proton spectrometer (LPS, FPS) or if the hadrons from the proton-dissociative system *Y* with a sufficiently high mass (>3–4 GeV) are observed in the forward part of the detector. Because the forward part of each detector has a beam-pipe hole, the smaller mass states *Y* will just escape undetected. In the case when the proton or its excitation escapes through the beam-pipe hole undetected, one needs to estimate the portion of the proton-dissociative events and subtract it from the visible cross section based on the Monte Carlo modeling. Such a procedure leads to sizeable systematic uncertainties.

If the Regge factorization decomposition (35) were exact, then the *t*-dependence from the $\gamma \longrightarrow V$ transition vertex and from the *t*-channel exchange will cancel in the ratio

$$\text{Ratio(el/diss)}$$
$$= \frac{d\sigma(\gamma p \longrightarrow Vp)}{dt} \Big/ \frac{d\sigma(\gamma p \longrightarrow VN)}{dt}, \quad (190)$$

which must be flavor-independent and controlled by the change of the *t*-dependence from $p \longrightarrow p$ to $p \longrightarrow Y$ transition [114]. Furthermore, the Regge factorization predicts that Ratio(el/diss) will not change from photoproduction of vector mesons to *pp* scattering:

$$\text{Ratio(el/diss)}\big|_{pp}$$
$$= \frac{d\sigma(pp \longrightarrow pp)}{dt} \Big/ \frac{d\sigma(pp \longrightarrow pN)}{dt} \quad (191)$$
$$\approx \text{Ratio(el/diss)}\big|_{\gamma V}.$$

In Fig. 59, the experimentally measured ratio Ratio(el/diss) is shown as a function of *t* for ρ, ϕ, and J/ψ mesons photoproduced at HERA. The same ratio for the *pp* reaction is shown as a comparison. All ratios coincide within the errors, which is consistent with the hypothesis of Regge factorization and lends a support to the separation procedure. The elastic reaction production dominates at $|t| \lesssim 0.4$–0.6 GeV^2, the proton-dissociative production takes over at larger $|t|$. Notice a close similarity to a comparison of the elastic and nucleus-dissociative *pA* scattering shown in Fig. 8. Figure 59 shows the typical interplay of the *t* dependence of the elastic and proton-dissociative production in electroproduction of J/ψ as measured by H1 [89]. One sees that the relative contribution of the proton-dissociative events is increasing rapidly with *t* making the
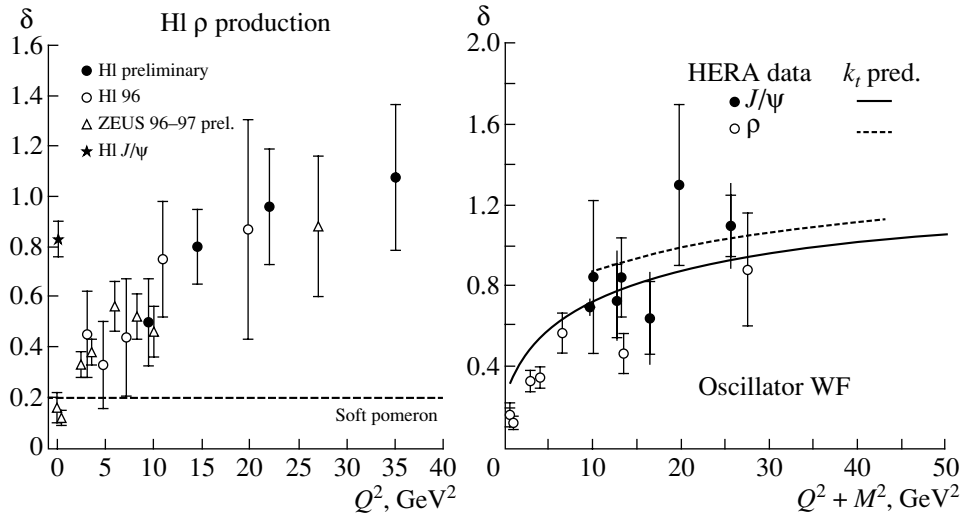

Fig. 53. The exponent δ of the fits $\sigma \propto W^{\delta}$ to the W dependence for the ρ production as summarized in [83] including the PHP J/ψ point from [70] presented as a function of Q^2 (left plot) and combined ρ and J/ψ data [71, 89, 90] presented as a function of $Q^2 + M_V^2$ in the right plot. The predictions from the k_t-factorization approach [54, 55] are also shown.

Fig. 54. The left box: tests of models for the small-x gluon density using the early HERA data on the energy dependence of J/Ψ photoproduction together with data from fixed-target experiments. The plot taken from [173] shows the pQCD calculations for the GRV95 [293] and MRS95 [294] parametrizations of the proton gluon density based on the pre-1995 data on $F_{2p}(x, Q^2)$ and illustrates the status of the subject at that time. The right box: the parametrization of the energy dependence of J/ψ production in the Fiore *et al.* model of a double-pole Pomeron with intercept $\alpha_P(0) = 1$ [229].

elastic measurement possible only at rather low t values (typically, $|t| < 0.6$–1.0 GeV^2).

At still larger momentum transfers, $|t| \geqslant 1$ GeV^2, the vector meson production is dominated by a proton-dis-sociative reaction. In addition, the production mechanism changes and the exponential fall-off of the differential cross section is superseded by the inverse powers of $|t|$ or $(m_V^2 + |t|)$.
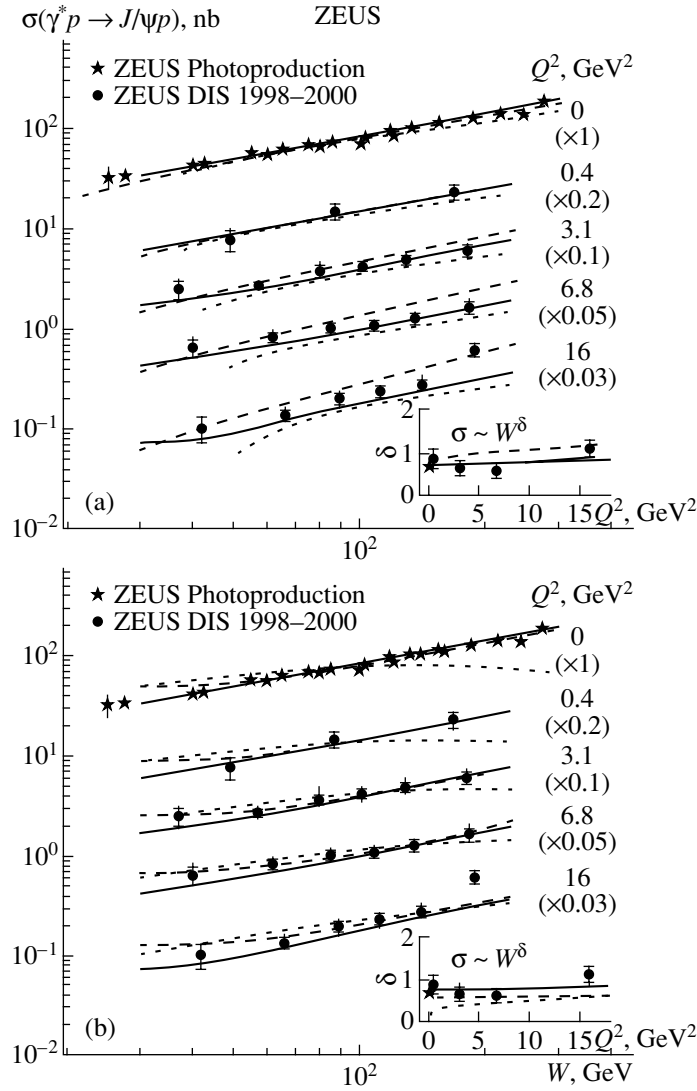

Fig. 55. The tests of the pQCD predictions for various models for the small-x gluon density of the proton versus the recent ZEUS data on J/ψ production as a function of W for different values of Q^2 [71, 90]. The curves in the top box represent the predictions of models MRT $\times$ 1.49 (solid curve), FKS $\times$ 1.7 (dashed curve), and GLLMN $\times$ 0.9 (dotted curve); the curves in the bottom plot are the MRT results based on different gluon densities in the proton: the solid curve, ZEUS-S $\times$ 1.49; the dashed curve, CTEQ6M $\times$ 2.22; the dotted curve, MRST02 $\times$ 2.98. All theoretical curves are rescaled as indicated above to fit the ZEUS photoproduction point at $\langle W \rangle$ = 90 GeV. The inserts show the exponent δ of the parametrization $\sigma \propto W^\delta$ for these models.

8.2. Diffraction Cone at Low t

8.2.1. The Diffraction slope versus hard scale: Theoretical expectations. The t-dependence of the differential cross section as small t is usually parametrized in terms of the diffraction slope b_V (see Eq. (34)). The fitted values of b_V depend slightly on the range of t, the more refined parametrization

$$\frac{d\sigma}{dt} \propto \exp(-b_V|t| - c|t|^2)$$

with the curvature parameter c allows one to extend the fits of the experimental data up to $|t| \sim 1$ GeV^2. The allowance for the curvature c does not shift the value of fitted b_V significantly. Several other definitions of the

effective slope can be encountered in the literature, e.g., the derivative of the logarithm of the differential cross section at $t = 0$,

$$b_V = \frac{1}{\sigma}\frac{d\sigma}{dt}\bigg|_{t=0},$$

or, less often, the definition in terms of the average momentum transfer squared, $\langle |t| \rangle$,

$$b_V = \frac{1}{\langle |t| \rangle},$$

they can differ from b_V defined by fits to Eq. (34) by 1–2 GeV^{-2}.

The decomposition (35) of the diffraction slope into the target transition, beam transition, and the t-channel exchange component is exact in the simple Regge model. Similar decomposition holds also in the $k_\perp$-factorization and color dipole approaches despite breaking of the strict Regge factorization. In photoproduction, the key point is the shrinkage of the $q\bar{q}$ state of the photon from light to heavy quarks accompanied by the related decrease of the radius of the ground-state vector meson (see Section 3.4.2), which entail the hierarchy of diffraction slopes

$$b_{J/\psi}^{el} < b_\phi^{el} < b_\rho^{el}. \tag{192}$$

The Q^2-dependence of the diffraction slope is driven by a decrease of the scanning radius r_S with Q^2 (see Section 3.4.2, Eq. (80)), and the Q^2-dependence of the Regge shrinkage term through the Regge parameter $W^2/(Q^2 + m_V^2)$ (see Section 4.5, Eq. (128)):

$$b(Q^2) = b_0 + 2\alpha_P' \log\left(\frac{x_0 W^2}{Q^2 + m_V^2}\right) + \frac{A}{Q^2 + m_V^2}. \tag{193}$$

For $x_0 = 8.3 \times 10^{-4}$ as defined in Section 4.5, $b_0 \approx B_N$ is the approximately flavor-independent contribution from the proton. The shrinkage of the diffraction cone is for the most part a property of the x_g-dependent skewed gluon density (see Section 4.5). Moreover, because the scaling violations do depend on x_g, the scanning radius and hard-scale $\overline{Q}^2$ will exhibit slight energy dependence, which will affect the energy dependence of the differential cross section [26, 299]. The net effect of such non-Regge corrections is a substantial reduction of the observed α_P' from the input $\alpha_{BFKL}' = 0.25$ GeV^{-2} in the parametrization (129).

According to Eq. (80), the diffraction slopes for different vector mesons should be close if taken at equal values of the scanning radius r_S or equal values of $(Q^2 + m_V^2)$ [25]. More detailed analysis in [26] has shown that for the J/ψ the diffraction slope is slightly smaller, by ~ 0.5 GeV^{-2}, than for the ρ at the same $(Q^2 + m_V^2)$. In addition, the arguments presented in Section 4.8 suggest a somewhat larger scanning radius and larger diffraction slope for the transverse amplitude $\mathcal{T}_{11}$ compared with the longitudinal amplitude $\mathcal{T}_{00}$. The effect has been suggested and evaluated for the first time in [26]. Even for light vector mesons at small Q^2, the expected difference is small, ~ 0.5–1 GeV^{-2}; for heavy vector mesons, the contribution to the diffraction slope from the scanning radius is small and the effect is negligible one.

The arguments of Section 3.1.5 are fully applicable to vector meson production. For the proton-dissociative

Fig. 56. A compilation of the exponents $\lambda_{tot}^\rho(Q^2) = \frac{1}{4}\delta(Q^2)$ and $\Delta(\overline{Q}^2)$ of Regge fits to the energy dependence of the ρ photoproduction cross section, $\sigma_\rho(Q^2) \propto (W^2)^{2\lambda_{tot}^\rho(Q^2)}$, and of the proton structure function [296, 297], $F_{2p}(x, \overline{Q}^2 = \frac{1}{4}(Q^2 + m_\rho^2)) \propto x^{-\Delta(\overline{Q}^2)}$, plotted against $(Q^2 + m_\rho^2)$, in comparison with the results from the $k_\perp$-factorization model [54, 55].

photoproduction, one expects a substantially smaller diffraction slope

$$b_V^{diss}(Q^2) = b_V^{el}(Q^2) - B_N. \tag{194}$$

The principal point is that the difference of diffraction slopes for the elastic and proton-dissociative reaction must be approximately Q^2 and flavor-independent.

8.2.2. Experimental results: real photoproduction. The experimental results on the diffraction slope b measured in photoproduction at HERA are summarized in Table 4.

The values of diffraction slopes depend on the t-region where the fits are performed, which is familiar from πp, pp scattering [111, 300]. The flavor dependence is consistent with the theoretical expectations described in Section 8.2.1: the diffraction slope rises with the size of the meson with the exception of the $\Psi(2S)$. The charmonium models [47, 48] suggest the radius of the $\Psi(2S)$ as large as the radius of the ϕ, so that the diffraction slope of elastic $\Psi(2S)p$ scattering would be the same as in ϕp elastic scattering. Then, in the naive VDM, one would expect $b_{\psi(2S)} \approx b_\phi$. In contrast to that, the counterintuitive

$$b_{\Psi(2S)} - b_{J/\Psi} \approx -0.5 \text{ GeV}^{-2} \tag{195}$$

Fig. 57. The ratio $r_V = \sigma_V(Q^2)/\sigma_{tot}(\overline{Q}^2)$ for the ρ production as function of energy for several values of $\overline{Q}^2 = \frac{1}{4}(Q^2 + m_V^2)$: the left-hand side plots show the experimental data on the ρ and J/ψ production [295]; the right-hand side plots show the corresponding theoretical expectations for the energy dependence of r_V [55].

was predicted in [26] on the basis of node effect [18]. The H1 results for both elastic and proton-dissociative $\Psi(2S)$ production [73] are consistent with this prediction. Within the experimental error bars, $\Delta b = b^{el} - b^{diss} \approx$ 4.5–5 GeV^{-2} is flavor-independent, which agrees perfectly with the theoretical expectation (56), (194) and must be contrasted to a strong flavor dependence of b_{el}.

Notice a very small $b_{diss}(\gamma p \longrightarrow J/\psi Y)$, which is consistent with the equally small slope for the double-dis-

sociative hadronic diffraction $pp \longrightarrow XY$ (for the compilation of the hadronic data from the fixed target to ISR energies, see [122, 123]).

8.2.3. Experimental results: Q^2-dependence of the diffraction slope. Figure 60 shows the Q^2-dependence of the diffraction slopes $b_\rho(Q^2)$ and $b_{J/\psi}(Q^2)$. In the case of the ρ-meson, a strong Q^2 dependence of the b_ρ is observed: $b \approx 11$ GeV^{-2} in the photoproduction limit and drops down to 4–5 GeV^{-2} in hard electroproduc-
Fig. 58. Schematic diagram of proton-elastic (left) and proton-dissociative (right) vector-meson production in *ep* interaction: $ep \longrightarrow eVp$ and $ep \longrightarrow eVY$.

tion. In striking contrast, in the case of *J/ψ* production, the Q^2-dependence is very weak or absent, $b_{J/\psi} \approx 4.5$ GeV^{-2} was found throughout the entire Q^2 range.

Figure 60 also shows the comparison between the elastic and proton-dissociative slopes in ρ meson production. One clearly sees an approximately Q^2-independent difference $\Delta b = b_\rho^{el}(Q^2) - b_\rho^{diss} \approx 4\text{--}5$ GeV^{-2} between the two data sets, which coincides with the photoproduction value shown in Table 4. This is an important confirmation of the theoretical expectation (194).

Figure 61 shows the above results for elastic slopes $b_\rho^{el}(Q^2)$ and $b_{J/\psi}^{el}(Q^2)$ plotted as a function of $(Q^2 + m_V^2)$. The strong flavor dependence obvious if one compares the photoproduction values $b_\rho^{el}(Q^2 = 0)$ at $b_{J/\psi}^{el}(Q^2 = 0)$ is dramatically reduced in the variable $(Q^2 + m_V^2)$. The theoretical curves are from the k_t-factorization model [55]. Because of flavor-dependent departure of the hard scale $\overline{Q}^2$ from the simple estimate (9), the theoretical predictions for the *J/ψ* are slightly lower than for the ρ. Similar results were found earlier in the color dipole model [26, 301]. The origin of the weak Q^2-dependence for the *J/Ψ* is in a very small contribution to $b_{J/\psi}^{el}(Q^2)$ from $b_{\gamma^*V}(Q^2) \propto r_S^2 \propto 1/(Q^2 + m_V^2)$ (see Eqs. (80), (193)).

The similar approximate $(Q^2 + m_V^2)$ scaling holds for the proton-dissociative reaction: the results for b_ρ^{diss} for the largest values of Q^2 in Fig. 60 are perfectly consistent with the photoproduction value for $b_{J/\psi}^{diss}$ from Table 4.

8.3. Shrinkage of the Diffraction Cone and the Pomeron Trajectory

8.3.1. The W-dependence in photoproduction. Figures 62 and 63 show the energy dependence of the diffraction slope b for the ρ and *J/ψ* photoproduction,

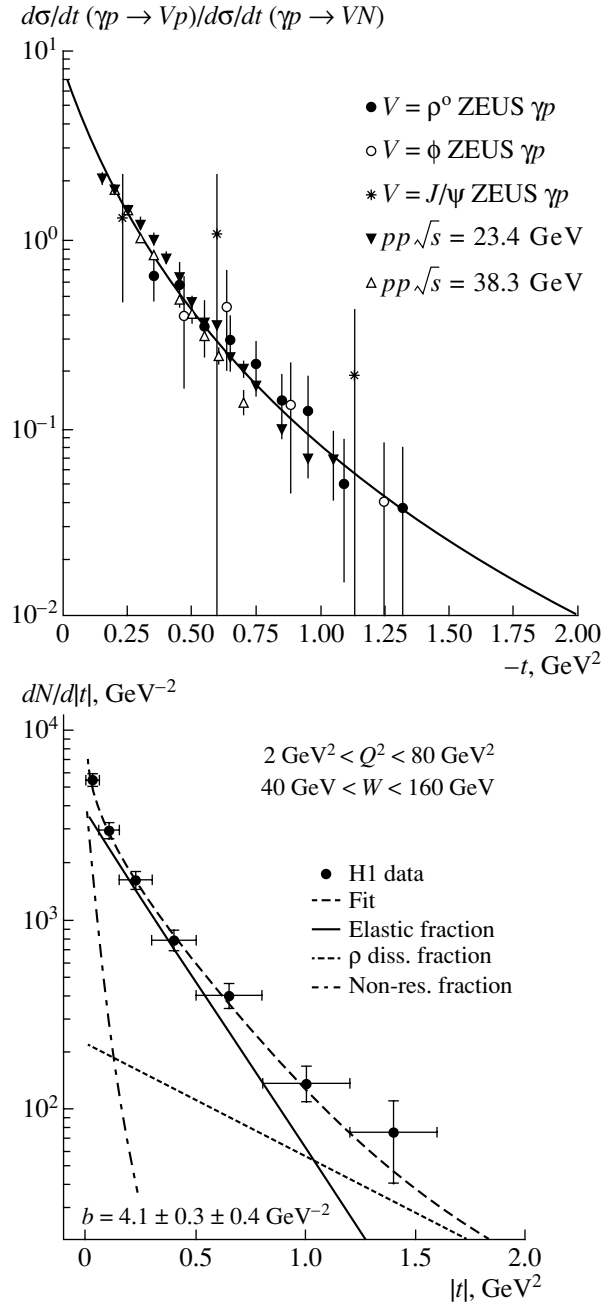

Fig. 59. Upper plot shows the ratio of elastic to proton-dissociative differential cross sections as a function of −*t* for vector-meson photoproduction [76], together with data from *pp* reactions [298] at $\sqrt{s}$ = 23.4 and 38.3 GeV. The curve is result of combined fit to all the data. Bottom plot presents the |*t*| distribution for the *J/ψ* sample as measured by H1 [89]. The dashed curve is result of a fit taking the background contributions into account. The full curve corresponds to the elastic contribution assuming an exponential distribution. The contributions from proton dissociation and nonresonant background are shown separately.

respectively. One sees a steady growth of the diffraction slope, i.e., the shrinkage of diffractive cone. When parametrized in terms of (37), the ρ photoproduction

data yield $\alpha'_P = 0.23 \pm 0.15(\text{stat.})^{+0.10}_{-0.07}(\text{syst.})$ GeV^{-2} [68]. This result for the soft reaction is consistent with $\alpha'_P = 0.25$ GeV^{-2} found in the simple Regge pole description of elastic pp scattering. The J/Ψ photoproduction must be regarded as a hard reaction; here, the evidence for nonvanishing α'_P is even stronger. Fitting to the form $b = b_0(90 \text{ GeV}) + 4\alpha'_P \ln\left(\dfrac{W}{90}\right)$ gave $\alpha'_P = 0.116 \pm 0.026(\text{stat.})^{+0.010}_{-0.025}(\text{syst.})$ GeV^{-2} [71].

8.3.2. The pomeron trajectory. In addition to fitting the differential cross section $d\sigma/dt$ at given W and evaluating the diffraction slope b as a function of W, one can study the W-dependence of the differential cross sections at fixed t. According to Eq. (28), the W-dependence of the differential cross section is $\propto W^{4(\alpha_P(t)-1)}$, so that one can extract α_P versus t, i.e., measure the effective trajectory $\alpha_P(t)$ of the t-channel vacuum exchange.

Figures 64 and 65 demonstrate the $\alpha_P(t)$ measured by ZEUS in the photoproduction of the ρ, ϕ, and J/ψ mesons. The obtained parameters of the effective Pomeron trajectories are:

$$\alpha_P(\rho; r) = (1.096 \pm 0.021) + (0.125 \pm 0.038)t,$$
$$\alpha_P(\phi; t) = (1.081 \pm 0.010) + (0.158 \pm 0.028)t,$$
$$\alpha_P(J/\Psi; t) = (1.200 \pm 0.009 \pm^{+0.004}_{-0.010}) \qquad (196)$$
$$+ (0.115 \pm 0.018 \pm^{+0.008}_{-0.015})t,$$

which must be compared with the DL parametrization (50). For all the vector mesons, the determined slope of the vacuum trajectory is significantly nonzero. Within the error bars, the value of α'_P appears to be insensitive to the particular type of the vector meson.

The dependence of the extracted Pomeron trajectory on Q^2 has been studied by ZEUS for the case of J/Ψ production. Figure 66 shows a comparison between the Pomeron trajectory at $Q^2 = 0$ and $Q^2 = 6.8$ GeV^2. The $k_\perp$-factorization predicts a slight increase of the effective intercept with Q^2 (see Fig. 46). Even if α'_{BFKL} in the parametrization (129) were a constant (the solutions of the color dipole BFKL equation [248] for the diffraction slope exhibit weak κ^2-dependence of α'_{BFKL}, though [25]), the above-described extraction will yield a weakly Q^2- and flavor-dependence values of α'_P.

Such non-Regge effects in the extracted α'_P have been evaluated in [55, 299] and demonstrated in Fig. 67. Because of the same non-Regge effects, the theoretical results for the effective vacuum trajectory are sensitive
Fig. 60. The preliminary ZEUS data on diffraction slope b for elastic and proton-dissociative production of the ρ [84] upper plot. Bottom plot shows the recent ZEUS [90] and H1 [89] data for elastic production of the J/ψ mesons as a function of Q^2.

to the wave function of the vector meson. The effect can be seen from at the bottom plot of Fig. 65; it is negligible for all the practical purposes.

8.4. The Gluon-Probed Radius of the Proton and the Pomeron Exchange Radius

The experimental data presented above on the diffraction slope for the J/Ψ production give

$$B_N = b_{2G} \approx (4\text{–}4.5) \text{ GeV}^{-2}. \tag{197}$$

It is a nonperturbative parameter which defines the form factor of the proton probed by color-singlet two-gluon current, $G_{2G}(t) \approx \exp\left(\frac{1}{2}b_{2G}t\right)$. It must be compared to the electromagnetic form factor $G_{em}(t)$, the familiar dipole parametrization for which $G_{em}(t) \propto 1/(\Lambda^2 - t)^2$ with $\Lambda^2 \approx 0.7 \text{ GeV}^2$ amounts to

Fig. 61. The diffraction slope b of elastic production of the ρ (H1 [16], ZEUS [68, 81]; the data from [84] are not shown) and J/ψ (H1 [89], ZEUS [90]) mesons as a function of $Q^2 + M_V^2$. The predictions from the k_t-factorization approach [54, 55] are shown.

$$B_{em} \approx \frac{4}{\Lambda^2} \approx (5.5\text{–}6) \text{ GeV}^{-2}. \tag{198}$$

The departure of b_{2G} from B_{em} must be regarded as a substantial one. The photon only couples to charged partons in the proton, whereas the gluonic form factor is sensitive to the distribution of all color charges—the (anti)quarks and gluons—in the proton. Should one interpret the observed inequality $b_{2G} < B_{em}$ as evidence for the gluonic lump in the center of the proton?

The same problem is present in πp, pp scattering. For instance, Schiz et al. find that, at 200 GeV, the observed t-dependence of scattering amplitudes is very well reproduced by the product of charge form factors of the beam and target particles [300]. One would interpret that, as an equality of the strong interaction and electromagnetic radii, $b_{2G} \approx B_{em}$, at this particular energy. However, in hadronic scattering, the shrinkage of the diffraction cone is rapid, and at lower energies ~10 GeV, still in the applicability domain of the Regge model, both $b_{\pi p}$ and b_{pp} are substantially lower than at 200 GeV, and one runs into the same problem with $b_{2G} < B_{em}$.

A very small value of the gluon radius of the proton, as a matter of fact, $b_{2G} \ll B_{em}$, has been found by Braun et al. from the QCD sum rules [302]. The QCD sum rule results depend on the interpolating field for the nucleon, though. Braun et al. take the $qqqg$ operator; whether the radius evaluated for the hybrid, higher
b_ρ, GeV^{-2}

Fig. 62. The diffraction slope b_ρ as a function of W for ρ photoproduction [69]. The continuous curve shows the result of the fit of the form (37) to the recent H1 measurement; other HERA and fixed-target measurements are shown for comparison; the extrapolation of the fit to the low W region is indicated by the dashed curve.

Effective slope, b (W)

Fig. 63. The slope $b_{J/\psi}$ as a function of W for J/ψ photoproduction as measured by ZEUS [71]. The results of the k_t-factorization calculations [54, 55] based on the oscillator (solid curve) and Coulomb (dashed curve) wave functions are compared with the data.

Fock component of the proton, applies to the whole proton or not remains an open issue.

Another small parameter which emerges in small-t diffraction is the Pomeron exchange radius, which is probed either in the double proton-dissociative pp scattering or in proton-dissociative vector meson production at small scanning radius r_S such as $\gamma p \longrightarrow J/\Psi Y$ of the ρ production in large-Q^2 DIS, $\gamma^* p \longrightarrow \rho Y$:

$$b_P \approx b(pp \longrightarrow XY) \sim b(\gamma p \longrightarrow J/\Psi Y)$$
$$\sim b(\gamma^* p \longrightarrow \rho Y) \sim 1 \text{ GeV}^{-2}. \tag{199}$$

The latter two reactions have a hard scale on the vector meson side, and one may link the anomalously small b_P to the small propagation radius of perturbative gluons $R_c \sim 1$ GeV^{-1}. The pp double diffraction reaction probes the soft Pomeron; why the soft and hard Pomeron exchanges have equally small exchange radius remains an open issue.

8.5. Beyond the Diffraction Cone: Large |t| As a Hard Scale

8.5.1. Large-t vector mesons as a Mueller–Navelet isolation of the hard BFKL exchange. The basics of the pQCD treatment, and helicity properties, of large-t vector meson production were reviewed in Sections 4.10 and 5.4. Here, we focus on the t- and W^2-dependence of the large-t cross section.

On the theoretical side, the large-|t| production of vector mesons is a very promising testing ground for ideas on the BFKL Pomeron, because the large momentum transfer Δ flows along the BFKL Pomeron from the target to the projectile. There is a close analogy to the long sought Mueller–Navelet isolation of the hard BFKL exchange by selecting DIS events with one hard jet in the target fragmentation region and the second hard jet in the photon fragmentation region [303]. Within the effective parton description of the proton-
dissociative $\gamma p \longrightarrow VY$, in terms of the elastic scattering $\gamma q \longrightarrow V q'$, the recoil quark (antiquark, gluon) with large transverse momentum Δ gives rise to the target hard jet of Mueller and Navelet, whereas the large-t vector meson is a substitute for the Mueller–Navelet hard jet in the photon fragmentation region. The vector meson production is even more advantageous, because one has access to larger rapidity gaps between the vector meson and the system Y than would be possible in the Mueller–Navelet two-jet process.

The pQCD two-gluon approximation misses the dependence on the rapidity gap, and the total normalization must be adjusted to the experimental cross section. Otherwise, as we will see below, it is doing a reasonable job on the t-dependence. The state-of-the-art BFKL-based calculations use Lipatov's leading-order fixed-α_S^{BFKL} approximation for the unintegrated off-forward gluon density. By the logics of the calculation, one may expect

$$\alpha_S^{\text{BFKL}} \sim \alpha_S(|t|) \tag{200}$$

and expect the Regge energy dependence (154) with the BFKL trajectory given by Eq. (59).

8.5.2. Theoretical expectations for flavor dependence at large t. A crude reinterpretation of very involved theoretical calculations [46, 53, 261, 304, 305] starting with the pQCD subprocess $\gamma^* q \longrightarrow V q'$ is as follows.
Fig. 64. Determination of the Pomeron trajectory from the reactions $\gamma p \longrightarrow \rho^0 p$ and $\gamma p \longrightarrow \phi p$. The dots are results of ZEUS measurements [76]. The solid curves are results of the linear fit. The DL parametrization for the soft Pomeron trajectory [108] is shown for comparison as a dashed curve.

First, the relationship between the cross section of the theoretical partonic subprocess $\gamma q \longrightarrow Vq'$ and the experimentally observed $\gamma p \longrightarrow VY$ involves the effective number of partons in the proton,

$$N_p(t) = \int_{x_{\min}}^{1} dx'(x')^{2(\alpha_P(t)-1)}$$

$$\times \left(\frac{81}{16} g(x', t) + \sum_f [q(x', t) + \bar{q}(x', |t|)] \right),$$ (201)

where the Regge dependence on x' is reabsorbed into the flux of equivalent partons. After $N_p(t)$ is factored out, one obtains the cross section of the partonic subprocess at a fixed energy $W_{\gamma q}$:

$$\left. \frac{d\sigma(\gamma q \longrightarrow Vq')}{dt} \right|_{W_{\gamma q} = W_{\gamma p}} = \frac{1}{N_p(t)} \frac{d\sigma(\gamma p \longrightarrow VY)}{dt}.$$ (202)

The cut $x_{\min} = 0.01$ used by ZEUS Collaboration [77] gives $N_p(t)$, shown in Fig. 68. H1 Collaboration [79] imposes the cut $M_Y^2 < M_{\max}^2 = 900$ GeV^2, which translates into

$$x_{\min} = \frac{|t|}{M_{\max}^2 + |t|}.$$ (203)

Evidently, for $\alpha_P(t) = 1$, the number of partons diverges as $x_{\min} \longrightarrow 0$, and at $x_{\min} = 0.01$, it exhibits a rise with $|t|$ because of the scaling violations in the gluon density (see Fig. 68). Opposite to that, for the H1

cut (203), the decrease of N_p with $|t|$ is driven by the rise of $x_{\min}$ (see Fig. 68). The sensitivity of N_p to the trajectory $\alpha_P(t)$ is very strong: for $\Delta_P = \alpha_P(t) - 1 = 0$, the true number of partons is very large, and is a steep function of $x_{\min}$; for $\Delta_P = 0.5$, the integral (201) is reminiscent of the momentum sum rule integral and yields weakly t-dependent $N_p \approx 2.5$ (see Fig. 68).

Second, in view of an approximate SCHC with dominant σ_T, the cross section must be proportional to $m_V^3 \Gamma(V \longrightarrow e^+e^-)$. That does not exhaust the flavor dependence, because the onset of the hard regime obviously does depend on the mass of the heavy quark. The pQCD two-gluon exchange approximation suggests that, for slow Fermi motion in vector mesons, the appropriate hard scale is

$$\overline{Q}_t^2 \approx (m_V^2 + |t|)$$ (204)

([261, 305] and references therein). Although the Fermi motion can change the coefficient in front of m_V^2, one must conclude that for the J/Ψ the large t means $|t| \gg m_{J/\psi}^2 \sim 10$ GeV^2. The numerical studies by Poludniowski et al. [261] show that, even for light mesons, the variation of the constituent quark mass from $m_\rho/4$ to $m_\rho/2$ to m_ρ changes the predicted cross section by a factor of ~2 even at $|t|$ as large as 10 GeV^2 (see Fig. 69).

Third, in the pQCD two-gluon approximation, the target quark is regarded as a pointlike one, and the t dependence is entirely due to the $\gamma \longrightarrow V$ transition
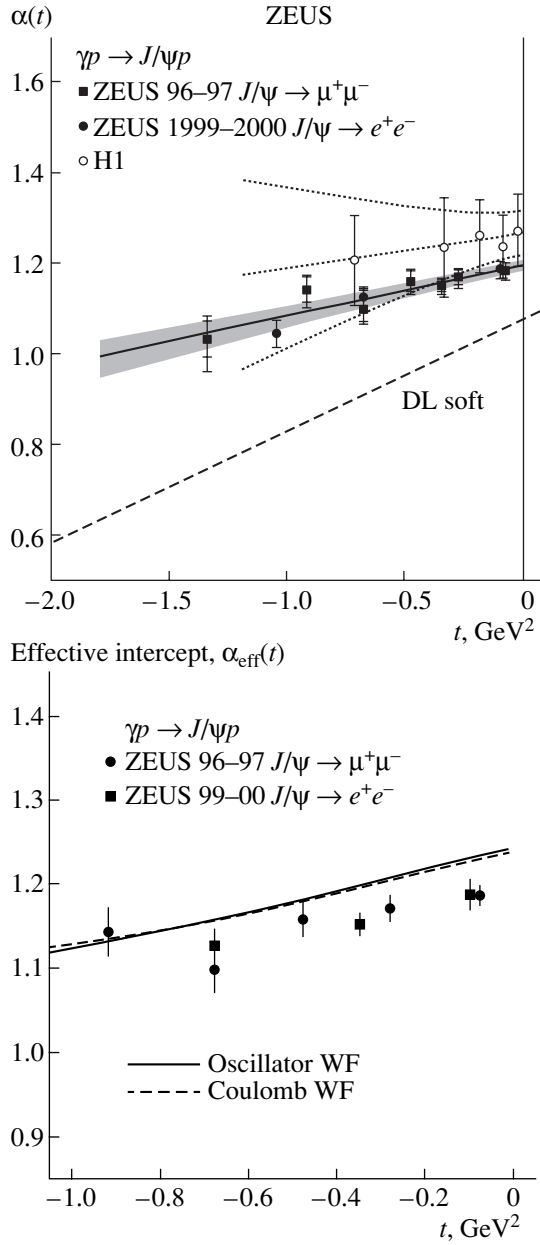

Fig. 65. Pomeron trajectory as obtained from J/ψ photoproduction measurements by ZEUS [71]. The results of H1 measurements [70] are shown for comparison. Linear fits to the ZEUS and H1 data are shown and compared with the DL parametrization for the soft Pomeron trajectory [108]. Bottom: the predictions from the k_t-factorization approach [54, 55] are compared with the ZEUS data.

Fig. 66. A comparison of the Pomeron trajectory extracted from the ZEUS data on real photoproduction and electroproduction of the J/Ψ [71, 90]. The solid curves are results of the linear fit. The Donnachie–Landshoff parametrization [108] of the soft Pomeron trajectory is shown for comparison as a dashed curve.

where we indicated the natural choice of the running couplings of gluons to the target quark, $\alpha_S(|t|)$, and to quarks in the vector meson, $\alpha_S(\overline{Q}_t^2)$. Based on the experimental data on vector meson decays [102], the prediction for flavor dependence of $d\sigma_V^{\text{diss}}/N_p(t)$ at identical values of the hard scale $\overline{Q}_t^2$ is

$$\rho : \omega : \phi : J/\psi$$
$$= 1 : 0.8 \times \frac{1}{9} : 2.1 \times \frac{2}{9} : 56 \times \frac{8}{9}. \tag{206}$$

Recall that, in the studies of the Q^2 dependence, one had to compare the cross sections at identical $(Q^2 + m_V^2)$.

Fourth, in the BFKL approximation, the target quark becomes effectively nonpointlike and introduces the approximately flavor-independent factor $\propto 1/|t|$ to the cross section, whereas the t-dependence from the $\gamma \longrightarrow V$ transition vertex will be weaker:

$$\left. \frac{d\sigma_{\text{BFKL}}(\gamma q \longrightarrow Vq')}{dt} \right|_{W_{\gamma q} = W}$$
$$\propto \alpha_S^2(\overline{Q}_t^2)\alpha_S^2(|t|)\frac{m_V^3 \Gamma(V \longrightarrow e^+e^-)}{|t|(\overline{Q}_t^2)^3}\left(\frac{W^2}{\overline{Q}_t^2}\right)^{2\Delta_{\text{BFKL}}}. \tag{207}$$

Consequently, the flavor dependence (206) at identical values of the hard scale $\overline{Q}_t^2$ must be tested for $|t|N_p^{-1}(t)(d\sigma_V^{\text{diss}}/dt)$ rather than $d\sigma_V^{\text{diss}}/dt$. Notice an extra suppression $\propto 1/(\overline{Q}_t^2)^{2\Delta_{\text{BFKL}}}$ coming from the

vertex with the hard scale $\overline{Q}_t^2$. Then, upon the x-integration in (151),

$$\frac{d\sigma_{2G}(\gamma q \longrightarrow Vq')}{dt}$$
$$\propto \alpha_S^2(\overline{Q}_t^2)\alpha_S^2(|t|)\frac{m_V^3 \Gamma(V \longrightarrow e^+e^-)}{(\overline{Q}_t^2)^4}, \tag{205}$$

Regge parameter. To run the strong couplings in (207) is to go beyond the accuracy of the scaling BFKL approximation.

8.5.3. The experimental results: measuring the trajectory of the hard BFKL pomeron. The *W*-dependence of the proton-dissociative vector meson production has been measured by both ZEUS and H1 collaborations.

The absolute *W* dependence of the *J/ψ* production has been measured by H1 Collaboration [79]. The experimental data are shown in Fig. 70; the results of the Regge fits are presented in Table 5. These results from H1 give solid evidence for $\alpha_P(t) > 1$ at large $|t|$. The found values of $\Delta_P = \alpha_P(t) - 1$ are close to the leading-order BFKL prediction with $\alpha_S^{\text{BFKL}} \sim 0.1$–$0.15$; a comparison with the NLO intercept is unwarranted at the moment. On the other hand, the large-*t* extrapolation of the ZEUS results (197) suggests $\alpha_P(t) < 1$ for $|t| \gtrsim 2$ GeV^2. (For the ρ and φ mesons, the similar cross-over takes place at $|t| \sim 1$ GeV^2; one would readily attribute that to the process being still soft.) Now, recall that the shrinkage at small *t* is driven by the infrared growth of α_S by which the low-*t* BFKL evolution becomes sensitive to the infrared region around the finite propagation radius R_c for perturbative gluons. In contrast to that, in the Mueller–Navelet large-*t* regime, the large momentum transfer $\sim\Delta$ flows through propagators of all *t*-channel gluons, the infrared contribution will be suppressed, and gross features of the fixed $\alpha_S^{\text{BFKL}} \sim \alpha_S(t)$, leading $\log\frac{1}{x}$, BFKL evolution will be recovered. One can fancy the nonlinear $|t|$ dependence of the vacuum trajectory of the form

$$\alpha(t) = 1.2 + (0.16 \text{ GeV}^{-2})t\frac{\Lambda^6}{|t|^3 + \Lambda^6} + 0.16\frac{t^4}{t^4 + \Lambda^8} \quad (208)$$

shown in Fig. 71 for $\Lambda^2 = 2.5$ GeV^2.

Ansatz (208) for the Pomeron trajectory turns over at $|t| \sim 1$–2 GeV^2, which is close to the natural scale $R_c^{-2} \sim 0.5$–1 GeV^2. The change of the sign of the derivative $\alpha'(t)$ from small to large *t* is supported by the ZEUS experimental data shown in Figs. 72 and 73. Although the *W*-dependence of the efficiency of the photoproduction tagger hinders the direct measurement of the absolute *W*-dependence and the determination of $\alpha_P(t)$ with the present ZEUS data [77], the large-*t* slope of the vacuum exchange trajectory can be measured in the tagger-independent manner,

$$\frac{(d\sigma(W)/dt)}{(d\sigma(W)/dt)|_{t=t_0}} \propto W^{4\alpha'(t-t_0)}. \quad (209)$$

The experimental data from ZEUS for this ratio and the values found for the slope of the vacuum trajectory α' are shown in Fig. 72. The summary of the low-*t* and

Fig. 67. The k_t-factorization model predictions [54, 55] for the Q^2-dependence of the slope of the effective Pomeron trajectory, α'_P, for the ρ [68, 76] and *J/ψ* [71, 90] production. The results for α'_P obtained from the study of cone shrinkage $b(W)$ and from the trajectory analysis $\alpha_P(t)$ are shown separately by open and filled dots, correspondingly.

high-*t* results for α' is presented in Fig. 73, where we also show $\alpha'(t)$ for the parametrization (208).

8.5.4. The experimental results: the t-dependence for a nucleon target. The *t*-dependence of the ρ, φ, and *J/ψ* meson proton-dissociative production cross section at high *t* is shown in Figs. 74 and 75. It is much slower than the exponential one typical of the diffraction cone and is in broad agreement with the inverse power law, as discussed in Section 8.2.

The quantitative interpretation of the experimental data taken at the moderately large *t* depends on the choice of the hard scale. A fit to the observed *t*-dependence in the form $d\sigma/d|t| \propto |t|^{-n_V}$ yielded for the ZEUS data [77] the exponents

$$n_\rho = 3.21 \pm 0.04(\text{stat.}) \pm 0.15(\text{syst.})$$
$$(\text{ZEUS}, 1.2 \text{ GeV}^2 < |t| < 10 \text{ GeV}^2); \quad (210)$$

$$n_\phi = 2.7 \pm 0.1(\text{stat.}) \pm 0.2(\text{syst.})$$
$$(\text{ZEUS}, 1.2 \text{ GeV}^2 < |t| < 6.5 \text{ GeV}^2); \quad (211)$$

$$n_{J/\psi} = 1.7 \pm 0.2(\text{stat.}) \pm 0.3(\text{syst.})$$
$$(\text{ZEUS}, 1.2 \text{ GeV}^2 < |t| < 6.5 \text{ GeV}^2). \quad (212)$$

which must be compared to $n_V \approx 4$ expected from the theory. The values of $|t| < 6.5$ GeV^2 in the ZEUS data on the *J/Ψ* production are arguably too small for the onset of the true large-*t* behavior. The *J/Ψ* production data from H1 [79] extend to $|t| < 30$ GeV^2 (see Fig. 75) and give the exponent
Fig. 68. The *t*-dependence of the effective number of partons $N_p(t)$ for the ZEUS (top box) and the H1 (bottom box) kinematical cuts for different values of the intercept $\alpha = 1 + \Delta$ [306]. Also shown are the curves for the *t*-dependent trajectory $\alpha_P(t)$ parametrized by Eq. (209) and shown in Fig. 71.

$$n_{J/\psi} = 3.00 \pm 0.08\,(\text{stat.}) \pm 0.05\,(\text{syst.})$$
$$\text{(H1, } 4.46 \text{ GeV}^2 < |t| < 30 \text{ GeV}^2). \tag{213}$$

A comparison of the results in (212) and (213) shows an importance of the finite mass effects in the *t*-dependence (see also Fig. 69). The theoretical calculations by Poludniowski *et al.* [261] within the scaling BFKL approximation are shown in Figs. 75 and 76 and clearly show an improvement from the pQCD two-gluon to BFKL approximation. The impact of the running strong coupling on the pQCD two-gluon results for the *t*-dependence is substantial; the BFKL calculations are for the fixed coupling. The results for the ϕ and J/Ψ are based on the parameters of the model which were adjusted to the ρ photoproduction.

8.5.5. The experimental results: the flavor and t-dependence for a partonic subprocess $\gamma q \longrightarrow q'Y$. The most direct test of the BFKL approach to large-*t* vector mesons is provided by the reanalysis [309] of the experimental data in terms of the cross section of partonic subprocess

Fig. 69. An example of the sensitivity of predictions for the ρ production cross section to the mass *m* of the quark in the vector meson [261].

$$|t| \frac{d\sigma(\gamma q \longrightarrow V q')}{dt}\bigg|_{W_{\gamma q} = W_{\gamma p}}$$
$$= \frac{|t|}{N_p(t)} \frac{d\sigma(\gamma p \longrightarrow VY)}{dt} \propto \frac{1}{\left(|t| + m_V^2\right)^{n_V}}. \tag{214}$$

Here, the residual *t*-dependence in the right-hand side probes the true dynamics of hard γV transition (see Eq. (207)). In such a representation, the scale-invariant BFKL approximation predicts the flavor-independent

$$n_V = 3 + 2\Delta_{\text{BFKL}} \approx (3.2\text{–}3.6). \tag{215}$$

The major problem with the extraction of the partonic cross section is that the absolute value and *t*-dependence of the number of effective partons $N_p(t)$ exhibits a strong sensitivity of the Pomeron trajectory (see Fig. 68). The resulting uncertainty propagates into the magnitude and *t*-dependence of the cross section of $|t| d\sigma(\gamma q \longrightarrow V q')/dt$ in (214) and, consequently, into the determination of the exponents n_V from the fit of the partonic cross section to the parametrization (214).

For consistency with direct experimental measurements of the Pomeron trajectory, one must use the parametrization (208), which correctly reproduces all the features of the H1 and ZEUS data shown in Figs. 71 and 73. The resulting fits to the ZEUS data [77] on the ρ, ϕ, and J/Ψ production at $\langle W_{\gamma p} \rangle = 100$ GeV yield $n_\rho = 2.08 \pm 0.06$, $n_\phi = 1.83 \pm 0.13$, $n_{J/\psi}(\text{ZEUS}) = 0.78 \pm 0.64$. In the H1 data [79] on the J/Ψ production, the energy $\langle W_{\gamma p}(t) \rangle$ slightly rises with *t* which introduces a certain bias into the *t*-dependence and enhances $n_{J/\psi}$. Neglecting that bias and excluding the point at lowest *t* yields $n_{J/\psi}(\text{H1}) = 2.55 \pm 0.2$.
Fig. 70. The H1 results for the J/Ψ photoproduction cross section as a function of $W_{\gamma p}$ in three bins of $|t|$ [79]. The inner error bars correspond to the statistical error, and the outer error bars are the statistical and systematic errors added in quadrature. The solid curves show the predictions from the BFKL model [307]; the dash–dotted curve is the result from the DGLAP model [308].

Fig. 71. A compilation of the ZEUS and H1 results on the determination of the Pomeron trajectory $\alpha_P(t)$ ($\Delta(t) = \alpha_P(t) - 1$) from the J/Ψ photoproduction. The solid curve shows a possible interpolation from the regime of shrinking diffraction cone at small t to the hard BFKL regime at large t.

The above cited error bars do not include the theoretical uncertainties of $N_p(t)$ connected to the parametrization of the t-dependence of $\alpha_P(t)$. For the sake of illustration, we cite here the results found if $N_p(t)$ is evaluated for fixed $\alpha_P(t) = 1 + \Delta_{BFKL} \approx 1.25$, although such a flat $\alpha_P(t)$ is inconsistent with the H1 and ZEUS data shown in Figs. 71 and 73. In this case, the t-dependence of $N_p(t)$ will be much weaker for both the ZEUS and H1 cuts (see Fig. 68); it does not change substantially with the further increase of Δ_{BFKL}. The partonic cross sections extracted from the same data will have a much steeper t-dependence, and the fitted exponents n_V will be substantially larger than for the Pomeron trajectory of Eq. (208): $n_\rho = 2.86 \pm 0.05$, $n_\phi = 2.66 \pm 0.12$, $n_{J/\psi}$(ZEUS) $= 3.88 \pm 0.62 \sim 3$ for the ZEUS data, and $n_{J/\psi}$(H1) $= 3.86 \pm 0.26$ for the H1 data. The statistical error bars in fitted values of n_V for the two choices of $N_p(t)$ are misleading, because the model dependence in the extraction of the exponent n_V of the t-dependence is much larger than the statistical error bars. In their scale-invariant BFKL calculations shown in Fig. 75, Poludniowski *et al.* [261] use fixed $\alpha_S = 0.25$, which amounts to even larger $\Delta_{BFKL} = 0.66$ and $n_V \approx 4.3$. Within those uncertainties, the data on different vector mesons do not exclude the flavor-independent n_V, and the observed t-dependence is not conflicting with the BFKL expectation (215).

A very large $\alpha_P(t) = 1 + \Delta_{BFKL} = 1.66$ used in the theoretical calculations [261] conflicts with the experimental data on the Pomeron trajectory shown in Figs. 71 and 73. Furthermore, the effective number of partons $N_p(t)$ evaluated with $\Delta_{BFKL} = 0.66$ is by the factor ~5–10 smaller than for the experimentally suggested trajectory shown in Fig. 71. This uncertainty is not discussed in [261] and casts a shadow on the agreement between the theory and experiment in the magnitude of the cross section. Before drawing firm conclusions on the status of the BFKL approach, one needs a much better understanding of the Pomeron trajectory and incorporation of the realistic Pomeron trajectory into the theoretical formalism.

The same model-dependence of the extraction of the partonic observable $|t|d\sigma(\gamma q \longrightarrow Vq')/dt = |t|(d\sigma(\gamma p \longrightarrow VY)/dt)/N_p(t)$ affects the discussion of the flavor dependence of large-t cross sections. First, the point that nei-

$|t|$, GeV

Fig. 73. HERA results on α' for the elastic and proton-dissociative (at $|t| > 1.3\ \mathrm{GeV}^2$) vector meson production [68, 71, 76, 77, 79] compared with the $\alpha'(t)$ from the parametrization (208). The reference value for soft hadronic interactions $\alpha'_{\mathrm{soft}} = 0.25\ \mathrm{GeV}^{-2}$ is shown as a dashed curve. The points are put in the center of $|t|$ range in which α' is measured. The vertical inner bars indicate the statistical uncertainty, and the outer bars represent the statistical and systematic uncertainties added in quadrature.

tion of $(|t| + m_V^2)$. Although the experimental data on the ρ, ϕ, and J/Ψ vector mesons do not have an overlap in $(|t| + m_V^2)$, it seems safe to extrapolate the ZEUS data on the ρ and ϕ production to $(|t| + m_{J/\psi}^2) = 12.5\ \mathrm{GeV}^2$ typical of the ZEUS data on the J/ψ production. The so extrapolated ρ and ϕ cross sections have the factor of ~ 2 uncertainty.

We recite from (206) the flavor dependence of $(1/N_p(t))(d\sigma_V^{\mathrm{diss}}/dt)$ at identical $(Q^2 + m_V^2)$ based on the vector meson decay properties:

$$\rho : \omega : \phi : J/\psi$$
$$= 1 : 0.8 \times \frac{1}{9} : 2.1 \times \frac{2}{9} : 56 \times \frac{8}{9}. \qquad (216)$$

If the number of effective partons $N_p(t)$ is evaluated with the Pomeron trajectory (208), which correctly reproduces the H1 and ZEUS data shown in Figs. 71 and 73, then the extrapolation of the ρ and ϕ cross sections to $(|t| + m_{J/\psi}^2) = 12.5\ \mathrm{GeV}^2$ gives the cross section ratios (within the factor ~ 2 extrapolation uncertainty)

$$\rho : \phi : J/\psi = 1 : \frac{1}{2} \times 2.1 \times \frac{2}{9} : \frac{1}{15} \times 56 \times \frac{8}{9}. \quad (217)$$

ther Q^2 nor $|t|$ are the correct hard scales to compare different vector mesons is illustrated by Fig. 77. Whereas, for light ϕ meson, the t-dependence, as well as the Q^2-dependence of the ratio σ_ϕ/σ_ρ is weak, the ratio $\sigma_{J/\psi}/\sigma_\rho$ changes by more than two orders of magnitude. The apparent approach to the $SU(4)$ ratios at the largest measured value $|t|$ is misleading—no true asymptotics can be reached at $|t| < m_{J/\psi}^2$.

Strong departure from the $SU(4)$ ratios is evident from Fig. 78, where we show the ZEUS and H1 data in the form of the partonic subprocess observable $|t|d\sigma(\gamma q \longrightarrow Vq')/dt = |t|(d\sigma(\gamma p \longrightarrow VY)/dt)/N_p(t)$ plotted as a func-
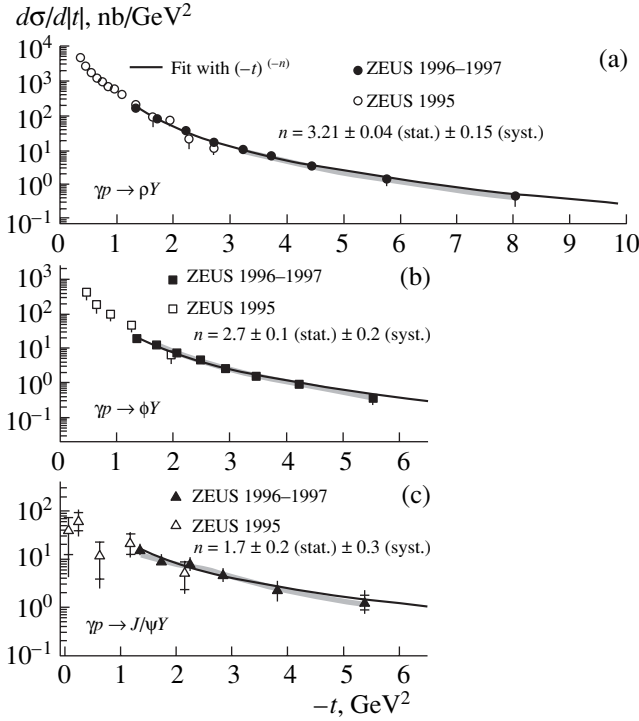

$d\sigma/d|t|$, nb/GeV^2

$-t$, GeV^2

Fig. 74. The ZEUS results for the differential cross sections $d\sigma_{\gamma p \to VY}/d|t|$ in the range $80 < W < 120$ GeV and $x > 0.01$ for ρ^0, ϕ, and J/ψ [77] production. The curves are results of the fit to the data with the function $A(-t)^{-n}$. The shaded bands represent the correlated uncertainties due to the modeling of the hadronic system Y.

If $N_p(t)$ is evaluated for $\Delta_{BFKL} = 0.25 = $ const, then the same extrapolation gives slightly different cross section ratios:

$$\rho : \phi : J/\psi \approx 1 : \frac{2}{3} \times 2.1 \times \frac{2}{9} : \frac{1}{7} \times 56 \times \frac{8}{9}. \quad (218)$$

For both the choices of the $N_p(t)$, the principal effect is an enhancement of the light vector meson production with respect to the J/Ψ production. Such an enhancement due to the chiral-odd $\gamma q\bar{q}$ transitions [242] is present in the calculations of Poludniowski *et al.* [261].

9. SUMMARY AND CONCLUSIONS

Slightly more than a decade ago, quite unexpectedly, HERA become a unique facility for exploring the diffractive physics in an entirely new domain of many different hard scales. Compared to the fixed-target data, the center-of-mass energy W, the explored regions of Q^2 and t were extended by one order of magnitude. By now, the principal features of the flavor-, t-, Q^2-, and W^2-dependences of the observed cross sections, polarization properties of produced vector mesons are well established. The high statistics of the HERA data allowed for the first observation of SCHNC in high-

Fig. 75. The differential cross section $d\sigma(\gamma p \longrightarrow VY)/dt$ for the J/ψ photoproduction at large t in the range 80 GeV $< W <$ 120 GeV and $x' > |t|/(900(\text{GeV}^2) + |t|)$ from H1 Collaboration [79]. The theoretical results for the pQCD two-gluon exchange with fixed and running α_S and scaling BFKL approximations are from Poludniowski *et al.* [261].

energy diffraction. Regarding the experimental situation, there is an overall consistency between the experimental data from H1 and ZEUS collaborations and the early data from fixed-target experiments.

What did change in our understanding of high-energy diffractive scattering, after that decade of amassing high-precision experimental data by H1 and ZEUS collaborations, at HERA? What was the impact of these data on theoretical ideas on high-energy vacuum exchange in the t-channel—the Pomeron? How strongly is the post-HERA pQCD Pomeron different from the pre-HERA Pomeron approximated by an isolated Regge pole with an intercept $\alpha_{\text{soft}} \approx 1.1$? Is our theoretical understanding of diffraction sufficient to get all the information we can, and would like to, from the available experimental data?

The scaling violation in inclusive DIS is a classical short-distance phenomenon dominated by scales $\sim 1/Q$ [124–126]. Thanks to the 1970s groundbreaking works by Fadin, Kuraev, Lipatov, and Balitsky [35–37], the theory was well prepared to the observed departure from the DGLAP evolution and the BFKL Pomeron reinterpretation of a steep small-x rise of structure functions discovered at HERA.

The principal virtue of diffractive vector meson production in DIS at HERA is that it is a short-distance dominated process. At small to moderate t within the diffraction cone, the short-distance property is quantified by a scanning radius r_S [17–20]; at large t, the short scale is set by $1/\sqrt{|t|}$. The early discussion of the importance of large-t photoproduction of vector mesons as a testing ground of ideas on the pQCD Pomeron goes
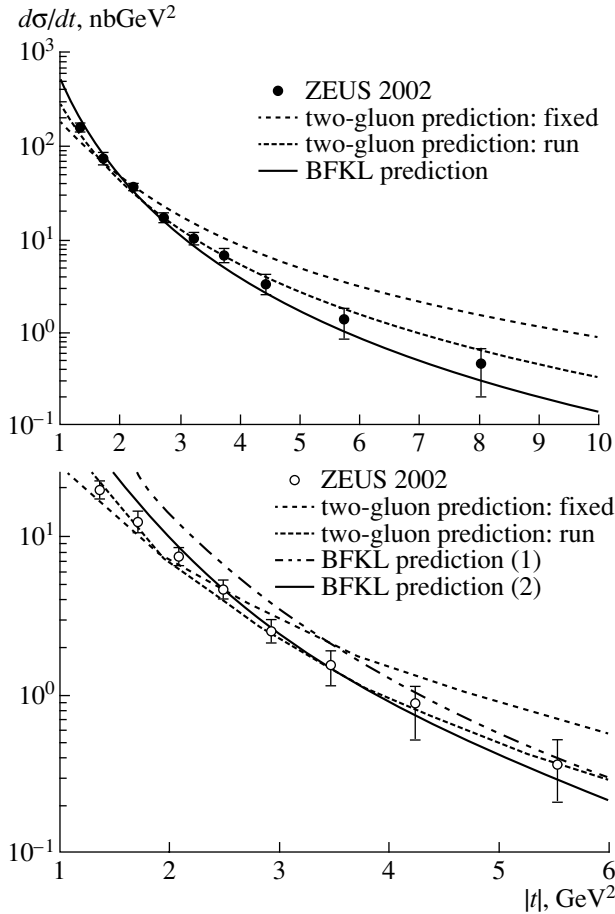

Fig. 76. The differential cross section $d\sigma(\gamma p \longrightarrow VY)/dt$ for the ρ (upper plot) and ϕ (lower plot) photoproduction at large t in the range 80 GeV < W < 120 GeV and x' > 0.01 from ZEUS Collaboration [77]. The theoretical results for the pQCD two-gluon exchange with fixed and running α_S and scaling BFKL approximations are from Poludniowski *et al.* [261].

back to mid-1980s work by Ginzburg *et al.* [30]. The idea of unified color dipole description of inclusive DIS and diffractive vector mesons, the concept of the scanning radius [17–20], and the importance of $\overline{Q}^2 = \frac{1}{4}(Q^2 + m_V^2)$ as a hard scale at small t [21, 22], and the possibility of vector meson production as a testing ground for models of gluon density in the proton emerged in early 1990s in works by Kopeliovich *et al.* [20] and Ryskin [22] and Brodsky *et al.* [23]. Ever since then, the collective effort by many groups has led to a fairly refined treatment of vector meson production at small to large $|t|$ and to an understanding of accuracy and limitations of the leading $\log\frac{1}{x}$ pQCD approaches. The wealth of the experimental data collected by H1 and ZEUS confirmed all the gross features of the pQCD-based description of the process.

An approximate $(Q^2 + m_V^2)$-scaling of all observables—total cross section [21], the diffraction slope [25], the exponent of the energy dependence [21]—alias the Pomeron intercept—has been the recurrent theme in our discussion of the experimental data; its experimental confirmation at HERA must be regarded as a major discovery and an undoubted success of the pQCD approaches. The pQCD dictated relationship between the energy dependence of vector meson production and inclusive DIS encoded in terms of the energy dependence of the gluon density [20, 22, 23] has been confirmed experimentally beyond reasonable doubt and is another major discovery at HERA.

Success with theoretical predictions of an absolute cross sections is a modest one. The $(Q^2 + m_V^2)$ as a hard scale for small-t diffractive vector mesons is entirely analogous to Q^2 as a hard scale in inclusive DIS. The pQCD only predicts the dependence on those hard scales starting from certain soft input. Within the color dipole and $k_\perp$-factorization approaches, this input is universal for vector meson production and inclusive DIS; still, it does not come from first principles of pQCD. Only one leg of the Pomeron, which couples to the γ^*V transition, rests on the hard pQCD ground; the second leg, which couples to a proton, is always in the soft regime. Once the $k_\perp$-factorization and other related pQCD model predictions are normalized to the J/Ψ photoproduction data, the description of the observed Q^2 and energy dependence of $\sigma_{J/\Psi}(Q^2)$ is close to a perfect one, which must be regarded as a real success of pQCD in the domain of hard diffractive scattering.

Nonetheless, a factor of ~2 sensitivity of pQCD model predictions to the wave function of vector mesons is a well-established limitation of the leading-order $\log\frac{1}{x}$ formalism and cannot be eliminated at the moment. The ratio of longitudinal and transverse cross sections, $R_V = \sigma_L/\sigma_T$, is an example of an observable which exhibits especially strong sensitivity to the wave function of light vector mesons [253]. A very good demonstration of the sensitivity to the wave function is a node effect in the $\Psi(2S)$ production [17–19], which suppresses the cross section, makes it grow with energy faster than the J/Ψ production and leads to counterintuitive inequality of diffraction slopes for the $\Psi(2S)$ and J/Ψ production [26]. Further tests of pQCD predictions for diffractive vector meson production call upon the development of NLO $k_\perp$-factorization formalism. This includes the theoretical understanding of the effect of higher Fock states in vector mesons and the derivation of the $k_\perp$-factorization impact factors for the γ^*V transition to NLO in $\log\frac{1}{x}$.

The works by Ivanov and Kirschner [212] and Kuraev *et al.* [170], in conjunction with Zakharov's

**Fig. 77.** (a) The ratio of the ϕ to ρ^0 cross sections as a function of $-t$ or Q^2. The ϕ/ρ^0 results as a function of $-t$ for proton-dissociative photoproduction from this analysis are shown with solid circles, and those from the ZEUS 1995 [76] measurement, with the solid squares. The shaded bands represent the size of the correlated uncertainties due to the modeling of the dissociative system, Y. Open triangles at $Q^2 \approx 0$ GeV^2 [278], $Q^2 = 7$ GeV^2 [86], and $Q^2 = 12.3$ GeV^2 [280] represent the ϕ/ρ^0 ratio of the elastic cross sections as a function of Q^2 from ZEUS, while the open squares represent those from H1 [87]. (b) The ratio of the J/ψ to ρ^0 cross sections as a function of $-t$ or Q^2. The same convention for symbols as for ϕ/ρ^0 ratio is used. Open triangles at $Q^2 \approx 0$ GeV^2 [282] and $Q^2 = 3.5$ and 13 GeV^2 [81] represent the ZEUS measurements, while the open squares represent those of H1 [16, 89]. The dashed curves correspond to the $SU(4)$ predictions, while the dotted and dash–dotted curves correspond to the pQCD values given by Eqs. (206) and (178), respectively.

Fig. 78. The t dependence of the large-t vector meson production measured by ZEUS [77] and H1 [79] presented as a differential cross section of the partonic subprocess $|t|d\sigma(\gamma q \longrightarrow Vq')/dt = |t|(d\sigma(\gamma p \longrightarrow VY)/dt)/N_p(t)$. The straight curves are results of the fit by Eq. (214); the lowest $|t|$ data point of H1 has been excluded from the fit. The left box shows the results for the number of effective partons $N_p(t)$ evaluated for the Pomeron trajectory $\alpha_P(t)$ of Eq. (208) shown in Fig. 71; the right box is for $N_p(t)$ evaluated for the fixed $\Delta_P = 0.25$.

[211] early pQCD motivated discussion of helicity flip in hadronic scattering, have led to an understanding of SCHNC as a generic property of high-energy scattering the origin of which does not require an applicability of pQCD. The emerging phenomenology of spin properties of diffractive vector mesons has been very successful at small t; the SCHNC in high-energy small-t diffractive scattering is still another major discovery at HERA. On the theoretical side, the chapter has not been closed—further studies of the impact of chiral-odd $q\bar{q}$ components in the photon suggested by Ivanov et al. [242] are in order. They were found to be crucial [261] for theoretical explanation of an approximate SCHC in
the large-t photoproduction data. Here, the BFKL-based phenomenology of the absolute normalization and t-dependence is in reasonably good shape; a fly in the ointment is a sign discrepancy in the helicity-flip amplitude found by Poludniowski et al. [261].

What new did we learn about the hard Pomeron trajectory? In inclusive DIS, the pQCD Pomeron can only be probed at $t = 0$, and one can not tell the difference

between the fixed branching point and the moving pole options for the Pomeron. In diffractive vector meson production, the full *t*-dependence of the Pomeron exchange can be probed. The experimental observation by ZEUS Collaboration of Gribov's shrinkage of the diffraction cone in *J/Ψ* production is important evidence for the hard Pomeron being a moving *j*-plane singularity—this is definitely the first important new finding on the hard Pomeron trajectory beyond the reach of inclusive DIS. One option is that the pQCD Pomeron is a sequence of isolated moving Regge poles, as advocated in the pioneering Fadin–Kuraev–Lipatov work on the BFKL Pomeron [35]. Unfortunately, the accuracy of the combined set of the proton structure function and vector meson production data does not yet allow one to resolve the fine structure of those poles. A theoretical discussion has been confined to the evaluation of the slope of trajectories of these poles [25]; the large-*t* behavior of trajectories remains an open issue. The color dipole approach predicts an approximately Q^2-independent shrinkage of the diffraction cone; there is a weak evidence for that from ZEUS measurements, but the experimental situation is not conclusive yet.

Large *t* as a hard scale brings in new opportunities. In this case, the pQCD Pomeron is expected to be in the hard regime all the way through from the target to γ^*V transition. The experimental information on large-*t* vector mesons is very exciting. The H1 data on large-*t* *J/Ψ* mesons gave very interesting evidence, also supported by ZEUS data, for the antishrinkage, $\alpha'_P < 0$, and the emergence of the hard BFKL Pomeron exchange with intercept $\alpha_P \sim 1.3$ at $|t| \gtrsim 3$ GeV^2. This is the second important new finding on the hard Pomeron trajectory beyond the reach of inclusive DIS. Such a transition from shrinkage to antishrinkage is plausible, but has not yet been explored theoretically. Here, important issues for future theoretical studies are the sensitivity of the turn over from shrinkage to antishrinkage to the infrared regularization of pQCD and its $(Q^2 + m_V^2)$-dependence. To this end, an experimental study of the interplay of two hard scales—$(Q^2 + m_V^2)$ and $|t|$—would be most interesting. The flavor and *t*-dependence of large-*t* cross sections does not conflict the estimates based on the leading-order BFKL approach [261], but higher-precision data are needed for more definitive conclusions.

To summarize, the program of diffractive vector meson studies at HERA was an exceptionally fruitful one. The matching theoretical development followed, though, still more work is needed: the pressing issues include the *t*-dependence of the Pomeron trajectory from small to large *t*, understanding the role of higher Fock states in vector mesons and derivation of NLO $k_\perp$-factorization, the further studies of helicity properties of large-*t* vector mesons. On the experimental side, new results on vector mesons are expected to run for several more years at HERA.

NOTE ADDED

After the main body of this review had been completed, D.Yu. Ivanov and his collaborators reported a long-waited NLO analysis of γ^*V production [310–312]. It is a very involved calculation and has not yet a full-fledged NLO $k_\perp$-factorization analysis, because the vector mesons have still been treated in the collinear approximation. The major expectation was that the NLO calculations would more reliably fix the magnitude of the production amplitude; specifically, the NLO amplitudes must have a stability window as a function of the so-called factorization scale. To this end, the NLO results exhibit a discouraging instability of the pQCD expansion. First, the NLO corrections are twice as large in magnitude, and of the opposite sign, than the LO amplitude of photoproduction of the *J/Ψ* [311]. Second, the NLO amplitude for the electroproduction of the ρ lacks an expected stability window versus the factorization scale [312]. A further analysis of NLO correction, for instance, studies of the sensitivity of the stability window to models for skewed parton densities, and an independent rederivation are called upon to clarify this important issue.
